Figure 9 (a) Headspace chromatogram of defective coffee beans on primary column (CW20M), (b) selected cut of a normal coffee bean, and (c) of a defective coffee bean on secondary column (SE-54). Compound 1 was responsible for the ''peasy'' off-flavor. (Reproduced from S. Nitz et al., 'Determination of Sensorial Active Trace Compounds by Multidimensional Gas Chromatography Combined with Different Enrichment Techniques', *J. Chromatogr.*, **471**, 173–185, © 1989, with permission from Elsevier Science.)

of enantiomers requires the use of standards or retention time libraries because mass spectra of enantiomers are identical.[115]

A considerable body of data has been assembled in the three areas for which some examples have been presented. Much of the information is published in specialty journals. The reader may want to contact the appropriate original sources for additional details.

4 COMPREHENSIVE TWO-DIMENSIONAL GAS CHROMATOGRAPHY

Conventional 2-D GC has inherent limitations. Single heartcuts yield unambiguous results. Narrow heartcuts obviously provide the highest resolution potential because the transferred effluent is likely to contain only a few components. As the window of the heartcut widens, the probability of overlap in the second dimension also increases. The basic tradeoffs have been demonstrated in Figure 8. Addition of an intermediate trap does not fundamentally change the situation. The primary advantage of an intermediate trap is its ability to reverse the effects of band broadening from the first column. To save time, users often cut multiple effluent fractions into the intermediate trap. This practice is usually acceptable if the different heartcuts are far apart. The chances of the mixing of compounds from different heartcuts on the secondary column depends primarily on the spacing of the cuts and the difference in stationary phase polarities. The chance of interferences is minimal if only widely distanced heartcuts are taken. Accidental overlap from adjacent fractions can be eliminated by diversion of the effluent into a series of parallel traps or into separate secondary columns. Both of these operational modes have problems. Multitrap arrangements require much time because analysis is sequential. Elution from the secondary column must be complete before the contents of the next trap are introduced. Parallel columns do not have this time penalty but the cost and complexity of the system increase.

The complete characterization of a wide boiling range sample can be accomplished by comprehensive 2-D GC. The term ''comprehensive'' implies that the entire sample is subjected to periodic heartcuts in a fashion analogous to routine GC/MS. The principle of the operation has been illustrated in Figure 3. In essence, effluent from the first column is injected at a fixed frequency into a single secondary column. The frequency of transfer is analogous to the scan rate in GC/MS. Dispersion in 2-D GC occurs according to stationary phase interaction as opposed to ''mass dispersion'' in GC/MS. Both processes are quite similar in principle. The implementation of comprehensive 2-D GC however is quite difficult. The major challenge comes from the need to inject the effluent into the second column as a series of narrow pulses, followed by rapid elution. Narrow pulses can be generated by several methods. The most straightforward approach is to use a valve, fluidic switch or similar device.[116] Diaphragm-type valves can produce precisely defined pulses at a high rate and are quite suitable for this purpose. Unfortunately, most of the sample is lost.[117,118] A more promising approach is the use of a modulator which is capable of both focusing and reinjection of the analyte. Figure 10 shows the basic arrangement of a comprehensive two-dimensional gas chromatograph based on this principle.[119] The modulator accessory is commercially available.[120] Components eluting from the first column are focused on a short section of a fused silica column which is coated with a thick layer of stationary phase. This device, called a modulator tube, is inserted between the columns. The components are released from the modulator tube and injected into the secondary column by application of heat transferred from a mechanical sweeper. The rate of movement of the sweeper is limited by the heater temperature and the heating time constant of the column. The primary column is usually a conventional capillary column which is programmed slowly. The secondary column typically is a narrow-bore, high-speed column capable of elution within a few seconds or tens of seconds. High speed is necessary because elution from the secondary column must be complete or nearly complete before the next injection can be made. Figure 11 presents some details on the formation of these pulses.[121] The process can be divided into four segments.

Figure 10 Schematic diagram of basic comprehensive 2-D GC instrumentation based on a mechanical sweeper: 1, inlet; 2, primary column; 3, heated slit of sweeper; 4, motor drive of sweeper; 5, column connectors; 6, modulator tube; 7, secondary column; 8, detector; 9, GC oven.

1. Accumulation. The analyte moving into the modulator tube forms a sharp leading edge due to stationary phase focusing.

Figure 11 Detailed view of chemical pulse formation: (a) accumulation; (b) cut; (c) focus; and (d) launch. PT, phase termination. (Reproduced by permission from Phillips et al.[121])

2. Cut. The slotted heater moves over the modulator tube holding the adsorbed sample and brings the substances dissolved in the stationary phase back into the gas phase.
3. Focus. The front of the ''plug'' moves slightly ahead of the steep temperature gradient formed by the slotted heater. It is self ''sharpening''.
4. Launch. The ''plug'' eventually reaches a section of uncoated tubing or the secondary column. The phase ratio and carrier gas velocity in this section are high. The substances start to move at high speed.

All of these processes overlap and are coordinated. Several critical steps must be harmonized to make this complicated procedure a success. The components in the modulator tube must be heated rapidly, i.e. the thermal response of the system must be fast. This requires that heat transfer is rapid. In essence, it is necessary to heat and cool the modulator tube in a fraction of a second. Fortunately, fused silica has low thermal mass. Time constants of the order of 100 ms can be achieved, depending on factors such as column dimension and the temperature of the slotted heater.[121] Effective heat transfer requires that the distance between the surfaces of the slotted heater and the modulator tube is minimized. Factors such as the dimension of the connectors between the columns and the modulator tube become critical.

Prior to the invention of the rotating heater, a metal coated electrically heated column was used for GC × GC modulation. Electrical heating of metal coated modulator tubes seems to be an attractive alternative to mechanical devices. Thermal modulation was the first approach that was used to produce narrow pulses.[122–125] Electrical heating is attractive because the amount of transmitted energy can easily be controlled. It is, however, difficult to match the thermal requirements of the fused silica with the thermal mass of the surrounding film of metal. Relatively high temperatures are required for the formation of narrow pulses. This places considerable stress on the fragile components and causes frequent burnout. Metal lined tubing and miniature wire coil heaters are more stable but heat transfer characteristics become unsatisfactory because of high thermal mass.[126]

Another approach for the formation of pulses by mechanical means has also been offered. It is based on cryogenic focusing and uses a movable trap.[127] The accumulation and focusing phases are combined.

Figure 12 Effect of thermal modulation or peak widths and peak intensities. The low and broad peak is not modulated. The high and sharp peaks are the result of modulation of the same compound. (Reproduced by permission from Beens et al.[132])

The substances are moving toward a gradient of low temperature and are retained until the cryotrap is displaced by mechanical movement. The substances are then launched by being exposed to the temperature of the environment in the GC oven. An external source of heat is not required. This system is referred to as a longitudinally modulating cryogenic system (LMCS). It seems to be versatile and effective.[128–130] A number of advantages are claimed for this approach.[131] The method seems to be particularly suitable for highly volatile compounds which may not experience the necessary degree of stationary phase focusing on a thick film modulator tube at ambient temperature. Data available at this time are insufficient to predict which of the two types of mechanical modulators will eventually become more successful.

Modulation provides some unexpected benefits. It is possible to reverse the effects of peak dispersion caused by

Figure 13 Presentation of data in comprehensive 2-D GC. The one-dimensional (collapsed) GC trace is displayed on the front plane. Sequential GC × GC traces are shown on the top; contour plots are shown on the bottom plane.[135] FID, flame ionization detection.

Figure 14 (a) Total ion GC × GC/MS of a marine diesel fuel sample. The *x*-axis (min) reflects volatility based retention on the apolar primary column (13 m × 0.10 mm × 1.3 µm, dimethylpolysiloxane); the *y*-axis (min) reflects polarity based retention on a polar secondary column (2 m × 0.10 mm × 0.10 µm, cyanopropylmethylpolysiloxane). Both columns programmed 30–250 °C at 0.5 °C min^{-1}. Run time 440 min. Thermal modulator programmed at $\Delta T = 100$ °C above oven temperature, velocity 0.2 rev s^{-1}, period 14.4 s. MS conditions: scan 45–350 amu, 2.43 scans s^{-1}. (b) Enlargement of box 1. (c) Enlargement of box 2. (d) Enlargement of box 3. The peaks in the chromatogram are represented in the bottom window by shapes corresponding to the molecular ion of each peak. (Reproduced by permission from Frysinger et al.[140])

Figure 14 (*Continued*)

migration in the primary column. In essence, a wide peak can be sharpened into a series of narrow peaks. Figure 12 shows an overlay of peaks from two experiments.[132] A wide peak with a peak width of approximately 30 s is focused and periodically reinjected into a secondary column in the form of narrow pulses. Because of the law of mass conservation, peak areas must be the same. The slices from the individual focus/reinjection cycles must be integrated and summed for quantitation. The benefit of the process is a better signal-to-noise ratio and thus lower detection limit.[133]

At the present time, data acquisition and presentation of signals of the type shown in Figure 12 still present problems. One must keep in mind that an enormous volume of data is generated at a very rapid rate. The situation may be comparable to the early days of GC/MS. Most electrometers on currently available gas chromatographs do not allow proper filtering and noise rejection.[134] In conventional GC instrumentation, the analog signal from the detector is translated into digital pulses which are subjected to a low frequency pass filter below being reconverted into the final output signal.[132] This process produces large time constants and conventional equipment may not be capable of following rapidly changing signals. To overcome the problem, the signal has to be extracted from the electrometer board before the band pass filter. This results in increased noise. Detection limits are improved but the gain is not as significant as one may expect by looking at Figure 12. Nevertheless, this problem can be solved, in principle, by the introduction of fast amplifiers. A new generation of fast electronics is currently being introduced to the market.

Figure 14 (*Continued*)

Quantitation and data treatment in comprehensive 2-D GC require a different approach. Figure 13 shows an excerpt from a hypothetical chromatogram.[135] Each peak is cut into slices which are then subjected to individual analysis in the second dimension. Signal A consists of a single component whereas signal B contains two individual substances. The data can be displayed as three-dimensional plots or as contour plots.[136] Integration requires summation of individual slices.

Groups of components with similar properties tend to fall into well defined planes within the chromatogram. This is a consequence of intrinsic sample dimensionally, a property predicted by Giddings.[137] Groups of components with similar structural features can thus be integrated by delineation of boundary conditions.[138] The chromatograms produce order.[139] Figure 14(a) shows an excerpt of a comprehensive 2-D GC chromatogram reflecting the C_{10} to C_{20} range of a petroleum distillate.[140] This chromatogram is particularly interesting because it represents the first application of a mass spectrometer as a detector in comprehensive 2-D GC. The *x*-axis and *y*-axis represent retention in the primary and in the secondary dimension, respectively. Components at the bottom of the chromatogram experience the lowest retention on the polar secondary column and are thus the least polar substances in the mixture. They represent alkanes. Figure 14(b) shows an enlargement from the chromatogram section delineated by box 2. Peaks A, B, and C are situated slightly above the group of substances at the bottom. They represent a homolog series of alkylcyclohexanes which are slightly more polar than *n*-alkanes and most of the branched alkanes. Figure 14(c) shows a vertical slice (box 1). Peaks E and F have the lowest and peak A has the highest retention on the polar stationary phase. These compounds, representing different structures, have been separated according to polarity. They have similar boiling points and are thus unresolved on the apolar stationary phase. Figure 14(d) corresponds to box 3 which is displaced in the *y*-direction. These substances are obviously quite polar. The schematic presentation at the bottom of the figure shows that compounds sharing similar features fall into well defined spaces. Mass spectra confirm the assignments. The order produced in the process can be a valuable aid in

(d)

Figure 14 (*Continued*)

identification. Software for display and integration of flame ionization detection based data has now been developed. It includes options such as interactive zoom in/zoom out features, visual clues for peak start/peak stop, peak area integration routines, etc.[138] The distribution of components in two-dimensional space can be predicted.[136]

4.1 Operational Aspects and Future Developments

At the present time, comprehensive 2-D GC is still in its early stages of development. The practicality of MS detection has been demonstrated but the scan rates of conventional mass spectrometers are too slow to deal with the high rate at which the data are being generated. A new generation of rapid scan time-of-flight (TOF) type mass spectrometers can solve this problem.[141] These instruments are capable of generating up to 100 scans per second. Flame ionization detection is the most practical approach at this time. It is necessary to adapt and miniaturize other detectors, in particular the electron capture detector, to the environment of comprehensive 2-D GC. Comprehensive two-dimensional gas chromatograms of complex mixtures such as PCBs are ordered.[142] Components are thus more easily identified than in chromatograms where the order of elution is not structured. Chemometric methods of data treatment such as the Generalized Rank Annihilation Method (GRAM) can be used to deconvolute reduced resolution chromatograms.[117,118] The required run-to-run retention time precision, signal intensity and similar factors can be met by comprehensive 2-D GC. Independent temperature programming of the individual columns can provide optimal use of space and provide truly orthogonal information.[143]

Many chromatographers are not familiar with comprehensive 2-D GC. Applications have been limited to demonstrations in the fields of petroleum analysis. Two short reviews have been published in the mid-1990s

on the subject matter.[28,144] A thorough up-to-date review emphasizing fundamental aspects of 2-D GC has appeared after original submission of this article.[145] It was initiated by J.B. Phillips who has since passed away. J. Beens consequently finished the review. The future development of comprehensive 2-D GC looks very promising.

ACKNOWLEDGMENTS

I would like to than E.B. Ledford and G.S. Frysinger for valuable input and help with some of the figures and references. The late J.B. Phillips freely shared his experiences and provided unpublished data. J.H. Sandy provided the data for Table 2.

LIST OF SYMBOLS

α	Selectivity and saturation
H	Height equivalent of a theoretical plate
k'	Capacity factor
L	Column length
m	Number of expected components
N	Number of theoretical plates
n_c	Peak capacity
p	Number of observable peaks
P_1	Probability of obtaining a single component
R_s	Resolution
s	Number of peaks containing a single component
θ	Variable, determined by retention time range

ABBREVIATIONS AND ACRONYMS

The success of a gas chromatographic analysis mostly depends on the sample preparation procedure. Biological and environmental samples are not suitable for direct analysis. Organic analytes can be separated from matrixes by extraction methods such as gas–solid, liquid–liquid, solid–liquid, purge-and-trap, headspace, solid-phase (SPE), solid-phase microextraction (SPME), supercritical fluid (SFE) and Soxhlet extractions. These extraction methods are called phase separation methods. Matrix solid-phase dispersion (MSPD) is a special highly efficient phase separation procedure for biological matrixes such as meat, liver, muscle, vegetables, etc. The aim of the extraction procedure is not only separation of organic analytes from matrixes but also concentration in another phase.

If the organic analytes contain protic (active) hydrogen (alcohols, carboxylic acids, amines, oxo compounds, etc.) some derivatization reactions, such as acylation, alkylation and silylation, need to be carried out first. The aim of the derivatization methods is to increase the sensitivity of detection and thermal stability of the organic analytes. The other aspect of derivatization is to reduce the polarity of the compounds.

1 INTRODUCTION

The most important part of gas chromatographic analysis is the preliminary sample preparation process. The sample preparation procedures for gas chromatography (GC) are divided into two main types:

- extraction methods
- derivatization methods.

The original samples are often too diluted, contaminated, complex, etc. and are thus not suitable for injection into the gas chromatograph.

In addition to the chemical properties of the samples, their physical characteristics also influence the preparation procedures. To analyze water or soil samples, some kind of extraction method is needed. Often, in order to increase the sensitivity of the analytical method, a derivatization step is included, particularly after extraction. The aim of the extraction is the separation of organic analytes from matrixes and their concentration in another phase. Derivatization methods need to be carried out first if the compounds contain protic (active) hydrogens (alcohols, oxo compounds, carboxylic acids, phenols, amines, etc.) as these compounds are not suitable for direct gas chromatographic analysis.

The most relevant extraction and derivatization methods are summarized in this article.

2 GAS SAMPLE PREPARATION

2.1 Monitoring Airborne Contaminants in the Atmosphere

Airborne organic contaminants can be collected on the surface of different types of adsorbent materials, such as activated charcoals, polymer adsorbents, molecular sieves, etc. or absorbed in suitable solvents. The adsorption of organic vapours on solids is used as a preconcentration method. The recommended collecting devices are adsorbent tubes, filter cassettes, and impingers. The sampling process is carried out with an oil-free sampling pump. The pumping time of the air sample

depends on the characteristics of the trapped compounds. The trapped compounds can be desorbed from the adsorbents with a solvent or by thermal desorption methods before analysis. These methods of monitoring organic vapours are used for occupational hygiene control.[1]

3 LIQUID SAMPLE PREPARATION

3.1 Liquid–Liquid Extraction

This method is used to analyze water samples. Although the instrument (a separation funnel) is simple, the method can be expensive due to the high cost of ultrapure solvents. A given volume of the water sample is shaken with a given volume of a suitable organic solvent so that organic micropollutants are transferred mainly into the organic phase (Figure 1). To increase the efficiency of the extraction and to avoid foam developing, sodium chloride is added to the sample before extraction. After separating the phases, most of the organic solvent is distilled off. This concentrating process is carried out in a Kuderna–Danish apparatus (Figure 2). The degree of concentration is calculated from the ratio of the initial volume of the sample to the volume of the concentrated sample. For example, for a 1 L water sample which is finally concentrated to 1 mL, the degree of concentration is 1000 for both micropollutants and impurities of the solvent. After a large number of extractions, storage and handling of solvent wastes can be environmentally hazardous. The Kuderna–Danish apparatus is used for the extraction of nonvolatile or less volatile components, because its operating temperature is higher than the boiling point of the solvent. Liquid–liquid extraction is losing its importance as nonsolvent extraction methods become more and more popular.[2]

Figure 1 Separation funnel.

Figure 2 Kuderna–Danish apparatus.

3.2 Purge-and-trap Technique

This method is excellent for extracting volatile organic components from water. Ultrapure gas is bubbled through a 5–20 mL water sample. Volatile organic compounds (VOCs) move with the gas bubbles and the flow is driven into a heatable adsorber column, where components adsorb at room temperature. Then, by heating the adsorber column, these components are forced into a cooled capillary column, where they condense. This process is called cryofocusing. Finally, by heating the capillary column to 200–300 °C, the components pass into the gas chromatograph. Benzene homologs benzene, toluene, ethylbenzene, and xylenes (BTEX) and volatile halogenides are analyzed with this method according

Figure 3 Scheme of purge-and-trap technique.

to the United States Environmental Protection Agency (USEPA) (Figure 3).

Since the whole sample can be analyzed, this extraction method is highly sensitive, plus it has the advantage of being a nonsolvent technique. The detection limit is nanograms per liter in the case of a few milliliter water sample. Commercial instruments are automatic.[3]

3.3 Headspace Extraction

This method is used for extracting volatile compounds. The water sample is placed into a vial, which is put into a thermostat. A sample is then extracted from the headspace at a given temperature, between 40 and 60 °C. Two techniques exist, known as static and dynamic (Figure 4). Headspace extraction is a nonsolvent and automatic method. In certain cases the purge-and-trap technique can be replaced by this method, because of its high sensitivity.

3.4 Solid-phase Extraction

With the exception of volatile compounds, the SPE method is widely used. The sample is passed through a short, packed column, where organic components adsorb or absorb (Figure 5). Then they are eluted with a small amount (2–10 mL) of solvent. Three types of packing material exist:

1. normal phase (mainly SiO_2, Al_2O_3, silicates and other inorganic adsorbents)
2. reverse phase, which contain chemically bonded liquid film on an inorganic, solid support
3. ion-exchange packing.

Depending on the chemical properties of the film, a preseparation (clean-up) phase may be possible.

Figure 4 Scheme of headspace extraction: (a) dynamic headspace; (b) static headspace.

SPE has many advantages over more traditional sample preparation techniques such as liquid–liquid extraction. The main benefits are

- reduced need for organic solvent
- ease of automation
- concentration of analytes
- high recoveries
- highly purified extracts, etc.

Use of the SPE technique has increased dramatically in the last ten years.[4]

3.5 Solid-phase Microextraction

Solid-phase microextraction (SPME) is the most rapidly developing field of environmental analysis. SPME techniques were originally used for extracting water samples, but the method is also suitable for examining the headspace of solid samples. This method is simple, fast and quite efficient. Only 5–20 mL of sample is necessary, while no solvent is needed. The degree of concentration is 10^2–10^5, depending on the circumstances. The essential part of the instrument is a thin, fused silica fiber with chemically bonded organic film on its surface (Figure 6). When the fiber is immersed into the water sample or kept

Figure 5 The steps involved in SPE. ■, Sample; ●, , matrix components.

Figure 6 SPME manifold.

in the sample headspace for a given time (2–30 min) with vigorous stirring, organic micropollutants absorb in the film, depending on their distribution coefficients. Finally, using the holder, the fiber is placed into the injector of a GC instrument, where components desorb at high temperature (200–300 °C).[5]

4 SOLID SAMPLE PREPARATION

4.1 Soxhlet Extraction

This is a classical extraction method used for solid samples. Vapor from the solvent moves up from a flask, which is heated. The vapor condenses on a condenser, and drops of the solvent fall back onto solid sample particles. Once the side-vessel is full, the solvent runs back to the bottom flask (Figure 7). This method is a so-called exhaustive extraction, but is very time-consuming (8–48 h). The method can be automated, and in commercial instruments it is possible to extract more than one sample at the same time.

4.2 Supercritical Fluid Extraction

In a phase diagram of a one-component system we can see the temperature and pressure intervals, where different phases are thermodynamically stable (Figure 8). The values at which two certain phases can be in equilibrium are given by the barrier lines. Above a given temperature (T_c, critical temperature) the two phases become one. Under special circumstances, when both temperature and pressure are higher than the critical values, materials are said to be in a supercritical state. Supercritical fluids have properties of both liquids and gases. Their diffusion and viscosity constants are similar to those of gases, while their densities are closer to those of liquids (see Table 1). Supercritical fluids are excellent solvents, because it is easy to manipulate their solvation properties by changing the temperature and pressure. A scheme of the supercritical fluid extraction (SFE) process can be seen in Figure 9.

In the field of solid sample analysis, SFE is becoming more and more popular. Its efficiency is similar to that of Soxhlet extraction, while the process lasts only 20–30 min.

Figure 7 Soxhlet apparatus.

Supercritical CO_2 is the most common solvent. The method can be automated.[6,7]

4.3 Ultrasonic-assisted Solid–Liquid Extraction

This sample preparation method is used for extracting compounds from contaminated soil samples. The process is based on cavitation in liquid media. The bubble generation caused by cavitation is similar to boiling and it contributes to the dispersion of the solid sample. Usually the ultrasonic source is immersed into the mixture. Since the moisture content of the solid sample is rarely high, it is recommended that the ultrasonic-assisted extraction is begun with a polar organic solvent (such as acetone) and continued with a nonpolar one (such as *n*-pentane).

Figure 8 Phase diagram of CO_2.

Table 1 Characteristics of gaseous, liquid, and supercritical states

	Gas	Liquid	Supercritical fluid
Density (d, g cm^{-3})	10^{-3}	1	0.3
Diffusion coefficient (D, cm^2 s^{-1})	10^{-1}	5×10^{-6}	10^{-3}
Viscosity (η, g cm^{-1} s^{-1})	10^{-4}	10^{-2}	10^{-4}

Figure 9 Scheme of SFE technique.

Fields of application are with total petroleum hydrocarbons (TPH), GC, BTEX, chlorinated VOCs, polycyclic aromatic hydrocarbons (PAH) and polychlorinated biphenyls (PCB).

4.4 Matrix Solid-phase Dispersion

Matrix solid-phase dispersion (MSPD) is a highly efficient sample preparation process for use with solid matrixes. It is a microscale extraction technique, which usually needs 0.5–1 g of sample. This method was developed to extract

Figure 10 MSPD procedure.

additive residues from biological matrixes such as meat, liver, muscle, vegetable, etc.

Homogenization of the sample is carried out with a bulk-bonded silica-based sorbent in a mortar, and mechanical shearing is used to disrupt the structure of the tissue (Figure 10). The homogenization step is followed by tedious liquid–liquid extraction procedures. Using a suitable solvent this method is highly selective.[8]

5 DERIVATIZATION METHODS FOR GAS CHROMATOGRAPHY

The aim of derivatization methods for GC is the substitution of active functional groups to increase or decrease volatility, to improve detectability and thermal stability, and to reduce the polarity of molecules.[9,10] There are three main methods in this field:

- acylation
- alkylation
- silylation.

5.1 Acylation

The acylation method is used for compounds that contain OH, SH and NH groups, and reduces the polarity of these molecules. General acylation reagents are perfluoro acid anhydrides, such as trifluoroacetic anhydride and pentafluoropropionic anhydride, and fluoroacetamides, such as *N*-methylbis (trifluoroacetamide). The detectability is increased by electron capture detection (ECD).

5.2 Alkylation

The alkylation procedure is used to modify acidic hydrogens, such as phenols and carboxylic acids. Perfluoroalkyl reagents improve the detectability while other alkylation reagents, such as dimethylformamide, reduce the polarity of compounds.

5.3 Silylation

Silylation is substitution of an active hydrogen for a trimethylsilyl group. The silylated derivatives are more volatile and more stable. This method reduces the polarity of the compound and reduces the possibility of hydrogen bonding. Many hydroxy, carboxy and amino compounds have been successfully measured after silylation. General silylation reagents include dimethyldichlorosilane, trimethylsilyl-*N*,*N*-dimethylcarbamate, trimethylchlorosilane, trimethylsilylimidazole, etc.

Infrared Spectroscopy: Introduction

Marianne L. McKelvy
The Dow Chemical Company, Midland, USA

Infrared (IR) spectroscopy provides one of the most versatile and useful techniques for the qualitative and quantitative characterization of most types of materials found in the solid, liquid or gaseous state. The general utility of this technique is reflected in the fact that many sections of the Encyclopedia contain articles dealing with the application of IR spectroscopy to that particular area, for example, the characterization of polymeric materials. This section, then, focuses on basic theory of IR spectroscopy and spectral techniques that may be applied to a broad range of chemical systems.

The origins of IR spectroscopy lie in the vibrational motions of atoms within a molecule. The sharply defined frequencies of these vibrations fall within the IR region of the electromagnetic spectrum, from 14 000 to 20 cm^{-1}. The most useful range for general problem solving lies between 4000 and 400 cm^{-1}, the mid-IR range. Specific applications in the near-IR, the region above 4000 cm^{-1}, are discussed in other sections of this Encyclopedia, most notably in articles titled **Near-infrared Spectroscopy, In Vivo Tissue Analysis by; Near-infrared Spectroscopy in Food Analysis; Near-infrared Spectroscopy in Analysis of Crudes and Transportation Fuels; Near-infrared Spectroscopy of Polymers and Rubbers** and **Infrared Spectroscopy in Process Analysis**.

When a sample is irradiated with IR energy, that energy will coincide with vibrational frequencies of functional groups within the molecule. When these vibrational motions include a change in the dipole moment of the molecule, IR absorptions occur. The pattern of these absorptions for a molecule, the IR spectrum, is generally unique for a particular compound. Comparison of the IR spectrum of an unknown material with that of known standards is a powerful identification tool. In the absence of standard spectra, the fact that many functional groups (C=O, C≡N, −OH, C=C, etc.) possess absorption bands that are characteristic of that moiety can be used to identify the material. The article **Interpretation of Infrared Spectra, A Practical Approach** discusses these concepts in detail.

Since the intensity of spectral absorbance is directly proportional to the amount of sample present (Beer's Law), IR spectra can also be used to make quantitative determinations of the amount of individual components in a sample mixture. These procedures can be as simple as a calibration curve that measures the intensity of a band in a sample with known path length to complex determinations of multiple components in a matrix. However involved the analysis, the existence of well-defined standards of the materials to be characterized is critical for good quantitative determination. The Encyclopedia's section on *Chemometrics* discusses these quantitative approaches in detail.

Modern instrumentation for acquisition of spectral data in the mid-IR largely consists of Fourier transform infrared (FTIR) instruments. The improved signal-to-noise and enhanced data acquisition speed of these devices has resulted in the replacement of wavelength-dispersive instruments with FTIR instruments. Additional technological improvements over the last decade have significantly lowered the cost of these instruments, making them highly affordable.

This improvement in signal-to-noise has allowed for the introduction of sampling accessories and coupled devices that further expand the analytical capability of the IR technique. Reflectance accessories have improved the ability to analyze surfaces at various depths of penetration. The IR microscope allows the routine collection of IR spectra of samples as small as ten micrometers. Reflectance accessories for the microscope extend this capability to surface analysis as well. Coupling of gas and liquid chromatographic systems to IR spectrophotometers has extended the range of sample types available for analysis. In addition to the articles in this section, applications of gas chromatography/infrared (GC/IR) and liquid chromatography/infrared (LC/IR) to the polymer and food industries are discussed elsewhere in the Encyclopedia (**Liquid Chromatography in Food Analysis; Gas Chromatography in Analysis of Polymers and Rubbers; Inverse Gas Chromatography in Analysis of Polymers; Coupled Liquid Chromatographic Techniques in Molecular Characterization**).

Spectral Data, Modern Classification Methods for discusses the difficulty of classifying spectral data, where there are a large number of variables (i.e. wavelengths) represented in each spectral case. Two strategies for dealing with this problem are presented: the use of high dimensional classifiers and reduction of the number of variables using feature extraction methods.

The article **Cavity Ringdown Laser Absorption Spectroscopy**, although not a traditional IR technique, is an introduction to this developing variant on absorption spectroscopy. This new technique promises to bring improved sensitivity to the measurement of chemical species in a broad range of environments, from molecular beams to plasmas.

Much of this section deals with the application of particular instrumental techniques to broad systems of chemical materials. In **Emission Spectroscopy, Infrared**, the theory of IR emission spectroscopy, spectrometer design and

experimental considerations for measurements of solids, liquids and gases are discussed.

Gas Chromatography/Infrared Spectroscopy presents light pipe, matrix isolation and direct deposition interfaces for GC/IR. Applications to several industrial problems are discussed. The importance of spectral searching and databases is considered. Finally, the future of GC/IR and double-hyphenated techniques is presented.

Infrared Reflection–Absorption Spectroscopy provides an overview of this technique and the analysis of material surfaces. Theory, experimental and instrumental considerations are discussed. Finally, this technique is compared to other surface techniques that provide vibrational spectroscopic information.

Interpretation of Infrared Spectra, A Practical Approach begins with detailed discussion of the origins of IR spectra and then examines the various functional group frequencies in detail. The third portion of the article is devoted to a discussion of the importance of sample context – history and chemistry – in the analysis. The paper concludes with some simple guidelines and thought processes to assist with spectral interpretation.

Theory of Infrared Spectroscopy presents a discussion of the theoretical basis of IR spectroscopy, group theory, and discussion of solvent effects and the impact of hydrogen bonding, crystallinity and chain length of polymers on IR spectra.

Liquid Chromatography/Infrared Spectroscopy discusses techniques for both flow cell and solvent elimination approaches to LC/IR. Applications of both types of systems, including gel permeation chromatography, on-line measurements and flow injection analysis, are reviewed. Discussion of future directions for this technique is included.

The theory and design of the IR microscope are presented in **Microspectroscopy**. A discussion of sampling techniques useful in the preparation of specimens for the microscope is included. Reflection measurements are discussed in great detail. IR imaging, including a discussion of current array detector technology as well as the outlook for future development, is included.

The article **Vibrational Spectroscopy for the Analysis of Geological and Inorganic Materials** pays particular attention to sampling techniques for these materials. Spectral assignments for metal oxides and salts, hydroxides and silicates are discussed in detail. Numerous references to historic/archaeological and planetary applications of IR spectroscopy are also cited in this paper.

Spectral Databases, Infrared presents the history and application of spectral databases to the interpretation of IR spectra. Many references to published spectral collections and digitized spectral libraries are included. Various algorithms for spectral identification are discussed in detail.

Cavity ringdown spectroscopy (CRDS) has developed rapidly during the last two decades and has been implemented for a variety of applications ranging from fundamental spectroscopic studies, trace chemical detection for environmental monitoring, combustion flame chemistry and plasma diagnostics, elemental and isotopic measurements, breath gas analysis, and fiber ringdown chemical and physical sensor development. A host of chemical species, including atoms, ions, molecules, clusters, and free radicals, have been studied by CRDS. The experimental ringdown scheme has also evolved from an original mirror-based format to various new forms for detection and analysis of analytes in either gas phase or liquid solutions. Recent research effort has also extended the CRDS approach for fiber optical sensor development. CRDS has become a mature spectrometric technique for a range of prototype and commercial instrumentation. This article provides a review of the latest developments in CRDS applications, specifically emphasizing new trends in elemental and isotopic analysis, plasma diagnostics, breath gas analysis, and new fiber ringdown techniques for sensor development. The introduction of cutting-edge laser sources into CRDS methods, the combination of CRDS with conventional analytical tools, and current CRDS instrumentation are also briefly discussed.

1 INTRODUCTION

In the original implementation of CRDS, a laser pulse was trapped in a high-finesse optical cavity formed by two high-reflectivity mirrors. The many round trips of the pulse within the cavity enhanced the absorption path length for a sample gas in the cavity by several orders of magnitude. The decay time for light in the cavity was used to determine optical absorption rather than the change in intensity of the light. Following its introduction by O'Keefe and Deacon in 1988,[1] CRDS has been implemented for the spectroscopic study of numerous species, including molecules, free radicals, clusters, atoms, and ions in a variety of

environments, such as chemical reaction cells, supersonic beams, high-temperature plasmas/flames, and material processing chambers. Research and applications relevant to CRDS have expanded the original experimental scheme to the use of novel optical cavities,[2–6] light sources,[7–10] methods of cavity excitation and shutoff,[11–17] and combinations with other traditional instruments.[18–27] Although ringdown-based commercial instrumentation has been realized, thus far, only in semiconductor manufacturing,[28] this technology has already shown much promise in a wide variety of application areas, such as detection of trace species in environmental monitoring,[29–34] plasma and flame chemistry diagnostics,[35–45] high-sensitivity elemental and isotopic measurements,[46–53] breath gas analysis for medical diagnostics,[54–56] and fiber ringdown techniques for sensor development.[57–65] CRDS has been applied in spectral regions ranging from the ultraviolet to the infrared by using different laser sources. CRDS coupled with a frequency comb technique demonstrated the capability of measuring numerous chemical species simultaneously.[66,67]

More than 10 review papers on CRDS have been published to date. The first historical overview of CRDS was published in a book edited by Busch and Busch.[68] This book contains many of the early publications on various aspects of CRDS. Berden et al. have given a comprehensive review on experimental schemes and applications of CRDS.[69] Scherer et al. reviewed early publications in fundamental spectroscopic studies using CRDS.[70] Miller and Winstead have reviewed atomic and analytical applications of CRDS.[71] Wagner et al. have reviewed early CRDS studies in the infrared spectral region.[72] The application of CRDS for kinetics studies has been reviewed by Atkinson.[73] The technological innovations of cavity ringdown have been discussed in Vallance's review.[74] Paldus et al. have given a historical review of CRDS development.[75] Recently, Mazurenka et al. have reviewed the powerful application of diode lasers in CRDS and its variant, cavity enhanced absorption spectroscopy (CEAS), also widely known as an integrated cavity output spectroscopy (ICOS).[76] Very recently, Wang has reviewed plasma cavity ringdown spectroscopy (P-CRDS) for elemental and isotopic measurements (Figure 1).[77]

The purpose of this article is to provide an update of the previous review[71] on the application of CRDS in analytical and atomic spectroscopy by Miller and Winstead in 2000. The discussion attempts to cover a wide range of applications of CRDS with a new emphasis in this article on environmental monitoring, the latest developments in P-CRDS for elemental and isotopic measurement, and combustion flame chemistry and plasma diagnostics. Emerging medical applications of CRDS and new fiber ringdown techniques for optical sensor development are new additions to the article. Finally, a brief update of the current status of ringdown commercialization/instrumentation is also presented.

2 THEORY AND OPERATING PRINCIPLES

2.1 Cavity Ringdown Spectroscopy

The number of experimental methods that are essentially based on the CRDS principle continues to grow. However, in its original form, CRDS is implemented by injecting and trapping a laser pulse in a stable optical cavity, which is formed by two highly reflective mirrors. The intensity of the light in the cavity decays exponentially with time at a rate determined by the round-trip losses experienced by the laser pulse. This intensity decay is monitored using a photomultiplier tube or a photodiode placed behind the second mirror, and the ringdown time is usually determined by fitting the observed waveform to a single exponential function. A schematic diagram of a typical experimental system is given in Figure 2. For the simplest case, when the dominant losses are the mirror reflectivity and absorption from a sample gas in the cavity, the time constant for the exponential decay is given approximately by

$$\tau = \frac{d}{c[(1-R)+\alpha l_s]} \tag{1}$$

where d is the cavity length, R is the reflectivity of the cavity mirrors, α is the familiar Beer's law absorption coefficient of a sample in the cavity, l_s is the length of the optical path through the sample, and c is the speed of light. For a gas filling the entire cavity, $d = l_s$. As the laser wavelength is varied, the ringdown time will decrease upon tuning to an absorption wavelength of the sample (e.g. when α increases). Alternatively, when the laser wavelength is fixed on resonance with an absorption wavelength of the sample, variations in α caused by changes in the analyte concentration are reflected in the ringdown time.

Figure 2 Basic optical configuration for cavity ringdown spectroscopy.

A "back-of-the-envelope" understanding of the time behavior from Equation (1) can be gained from an examination of Figure 2, where the first few passes of a laser pulse through the cavity are depicted. When a laser pulse is incident on the first cavity mirror, most of the energy is reflected away from the cavity. Assuming that the fraction of the original pulse that enters the cavity has intensity I_0, after one pass through the sample gas, the intensity will be reduced according to Beer's law to $I = I_0 e^{-\alpha l_s}$. Following reflection from the second cavity mirror, the intensity will be reduced by the finite mirror reflectivity to $I = I_0 R e^{-\alpha l_s}$. After n round trips through the cavity and substituting $R^{2n} = e^{2n \ln R}$, the intensity will be

$$I = I_0 R^{2n} e^{-2n\alpha l_s} = I_0 e^{-2n(-\ln R + \alpha l_s)} \tag{2}$$

If the cavity is long enough that the pulse never overlaps itself (e.g. longer than one-half of the physical length of the laser pulse), a series of separated pulses decaying in time will be detected according to Equation (2).[70] In many cases, due to electronic response time or the use of shorter cavities, separated pulses are not detected, but rather a continuous exponential decay. The peak envelope of the separated pulses or the time constant for a continuous exponential decay can be found by converting from the discrete variable n to a continuous variable t such that $n = t/T$, where $T = 2d/c$ is the pulse round-trip time in the cavity. In this case, we have

$$I = I_0 e^{-tc(-\ln R + \alpha l_s)/d} \tag{3}$$

Of course, the absolute intensities detected by the Photomultiplier tube (PMT) are reduced by an additional factor of the mirror transmission, but this does not affect the time behavior of the exponential decay. From Equation (3), we see that the characteristic time for the laser pulse decay is given by Equation (4):

$$\tau = \frac{d}{c(-\ln R + \alpha l_s)} \approx \frac{d}{c[(1 - R) + \alpha l_s]} \tag{4}$$

as given in Equation (1). While this analysis does not provide a complete development of the technique, it captures the essential elements that yield the excellent sensitivity offered by CRDS. The performance and some limitations of CRDS and this simple model are discussed. Note that if the ringdown time is measured in the absence of a sample gas in the cavity (e.g. $\alpha = 0$), the reflectivity of the mirrors can be determined. Once the mirror reflectivity has been measured and a sample introduced, CRDS provides an absolute measure of the absorbance αl_s, from which the absolute density n of the absorber is determined by

$$\alpha l_s = \sigma n l_s \tag{5}$$

where σ is the absorption cross section of the absorber in the laser wavelength. This self-calibrating feature can serve as a great benefit in comparison to other high-sensitivity techniques, such as laser-induced fluorescence (LIF) or resonantly enhanced multiphoton ionization (REMPI).

2.2 Sensitivity

The high sensitivity of the CRDS technique stems significantly from the large number of passes the light pulse makes through the sample in the cavity. For mirrors of 99.99% reflectivity in a 1-m-long cavity, the ringdown time is approximately 33.4 μs for an empty cavity. This is equivalent to a 10-km path length traveled during the first time constant. For analytical applications, the detection sensitivity of CRDS is normally characterized by the detection limit, which is determined by a minimum detectable absorbance,[78]

$$\text{Absorbance} = \sigma n l_s = (1 - R)\frac{\Delta\tau}{\tau} \tag{6}$$

where $\Delta\tau$ is the difference between τ_0 (the decay time with no analyte) and τ (the decay time with analyte present). Equation (6) indicates that for a given mirror

reflectivity, the measured absorbance depends upon the quantity, $\frac{\Delta\tau}{\tau}$. When τ is replaced by τ_0 and $\Delta\tau$ replaced by σ_τ (one standard deviation of the measured ringdown time), then the absorbance in Equation (6) represents the minimum detectable absorbance based on a $1\sigma_\tau$ criterion. Note that in most cases the detection limit is derived on the basis of the standard $3\sigma_\tau$ criteria, namely,

$$A_{\min} = (1 - R)\frac{3\sigma_\tau}{\tau_0} \tag{7}$$

Clearly, Equation (7) demonstrates that increased mirror reflectivity and a more stable baseline (no analyte) ringdown time will improve $A_{\min}$. Here, σ_τ and τ_0 may be the values determined after averaging a number of individual ringdown measurements, further improving $A_{\min}$. Alternatively, sensitivity can be also characterized by a detection limit that explicitly includes the assumption that the single decay measurement uncertainty is improved by averaging over N ringdown events,[79] as given in Equation (8):

$$A_{\min} = (1 - R)\frac{\Delta\tau}{\tau\sqrt{N}} \tag{8}$$

If the measuring time is restricted to 1 s, then N is replaced by data collection frequency, f. Thus, the unit of $A_{\min}$ is $\mathrm{Hz}^{-1/2}$. This is also called *noise-equivalent minimum detectable absorbance*.

Examining Equations (1) and (5), one can see that the detection sensitivity is determined by a ringdown system's physical parameters, such as cavity length, sample path length, mirror reflectivity, and by the system electronic noise. Higher mirror reflectivity, longer sample path length, and lower electronic noise will improve detection sensitivity. The combined effect of the electronic noise with the optical alignment of the ringdown system is often experimentally characterized by $\sigma_\tau/\overline{\tau}$, which is typically referred to as the *ringdown baseline noise*. For a pulsed-CRDS system, the baseline noise is typically larger than 0.3%. However, for a continuous wave cavity ringdown spectroscopy (CW-CRDS) system, the baseline noise can be much lower. The lowest baseline noise reported thus far is 2.7×10^{-4} obtained in a near infrared (NIR) CW-CRDS system with an average over 300 ringdown events.[54] Detection sensitivity on the order of 1×10^{-8} (absorbance) demonstrated in the early studies[80,81] can now be readily achieved with the availability of ultrahigh reflectivity mirrors.

2.3 Cavity Design and Cavity Ringdown Spectroscopy Implementation

The simple model outlined in Section 2.1 neglects a number of other potentially important considerations. First, to achieve true single exponential behavior, the conditions for Beer's law behavior must be fulfilled.[78] These conditions include requiring that the frequency linewidth of the laser source be narrower than the absorption linewidth. If the laser source linewidth is broader than the absorption, then only that part of the laser frequency resonant with the absorption will be attenuated. The nonresonant frequencies of the laser pulse will continue to propagate in the cavity without being absorbed, leading to distinctly nonsingle exponential behavior. In the case where the absorption and laser linewidths are nearly the same, CRDS can still be used to extract quantitative information so long as the absorption constitutes a small portion of the total cavity loss (e.g. the absorption is small compared to losses at the mirrors).

The more detailed response of CRDS to the effects of cavity design and implementation was the subject of much discussion in the early CRDS literature.[49–51,78,82,83] A ringdown cavity is a high-finesse etalon, and, as such, possesses a discrete mode structure dependent upon the design of the cavity. For a cavity constructed from two spherical surface mirrors of radius R_1 and R_2 separated by a distance L, the frequencies of the stable cavity modes are given by the equation[52,84,85]:

$$\upsilon = \frac{c}{2L}\left\{n + (1 + m + l)\frac{\cos^{-1}\sqrt{(g_1 g_2)}}{\pi}\right\} \tag{9}$$

where $g_1 = 1 - \frac{L}{R_1}$ and $g_2 = 1 - \frac{L}{R_2}$. The parameters g_1 and g_2 are dimensionless quantities that can be used to determine whether a given cavity design is stable. For a stable cavity, the condition $0 < g_1 g_2 < 1$ must hold. In Equation (9), n, l, and m are integer quantities used to index the modes of the cavity. The parameter n represents the longitudinal mode number and is approximately of the order of $2L/\lambda$, l and m represent the transverse mode numbers. For the lowest order mode, commonly referred to as TEM_{00}, l and m are zero. Here, we see that for a cavity constructed from plane parallel mirrors where R_1 and R_2 are infinite, we recover the well-known frequency transmission of the Fabry–Perot type of etalon

$$\upsilon = \frac{nc}{2L} \tag{10}$$

The frequency structure of the cavity modes can be visualized as consisting of TEM_{00} longitudinal modes whose frequency separation is given by Equation (10) as $c/2L$. The frequency space between these TEM_{00} modes will be filled to a greater or lesser degree by higher order transverse TEM_{lm} modes, depending upon the exact design of the cavity. When a cavity is subjected to excitation by a very narrow-linewidth continuous wave (CW) laser, not all laser frequencies are transmitted

through the cavity.[86] Only those frequencies that correspond to stable modes of the cavity are transmitted. The behavior of such a cavity under pulsed excitation was also the subject of much discussion.[49–51,78,82,83] Arguments have been presented that the short coherence length of pulsed lasers, in general, precludes mode effects.[82] Other concerns have been expressed that for the absorption features narrower than the mode spacing of the cavity, it is possible that absorption features could be missed (since only light at the mode frequencies rings down in the cavity).[87] In practice, however, for pulsed laser excitation, such effects have not been problematic. Cavities can be easily designed to possess a near continuum of transverse modes.[88] Typical pulsed laser linewidths are also wider than even the normal spacing between the TEM_{00} longitudinal modes, so that light from the pulsed laser is injected into the cavity regardless of laser frequency or transverse mode structure. Finally, it has been noted that while mode effects may modulate the total intensity of the signal exiting the cavity, the signal usually never drops to zero.[89] Since the ringdown time and not the intensity is monitored in CRDS, a small modulation does not greatly hinder the ringdown measurement.

3 INSTRUMENTATION

3.1 Ringdown Cavities

A ringdown cavity in its original form consists of two high-reflectivity mirrors with a mirror spacing that meets the stable cavity conditions discussed in the preceding section. Nowadays, a ringdown cavity can have various forms, such as a cavity consisting of more than two high-reflectivity mirrors,[90] a pair of superpolished prisms,[3] a single piece of prism,[2] a section of single-mode optical fiber with two identical fiber Bragg gratings inscribed on it,[4] a fiber loop,[91] or a cavity with a plasma[18] or a flame in it.[86] Although there are many forms of ringdown cavities, the fundamental characteristics remain the same: laser light is trapped in a high-finesse cavity to experience many round trips to enhance the measurement sensitivity. Owing to different geometries and/or different cavity configurations, experimentally observed ringdown times can range from nanoseconds to hundreds of microseconds. Berden demonstrated an extremely short ringdown cavity (3 cm) in 1998.[92] Le Grand and Le Floch reported a very long cavity (270 cm) in 1990.[93] A cavity used to demonstrate a compact acetone detection device was only 13 cm in length (Figure 3), which yielded a ringdown time of 700 ns in the deep ultraviolet (UV) region.[55] For liquid detection, cavity lengths can even be on the order of μm. Conversely, using ultrahigh reflectivity mirrors in the infrared (IR) region, e.g. 99.9985%, a 43-cm cavity had a ringdown time of up to 100 μs,[28] and a ringdown time of several hundreds of microseconds has been reported in a fiber loop ringdown system.[94]

Figure 3 A compact ringdown cavity for CRDS prototyping. (*Appl. Spectrosc.*, 2004, **58**, 784–791 by Wang et al., Figure 2 on page 786.)

Often a mirror-based ringdown cavity can only be used for measurement of a very limited number of species because of the relatively narrow bandwidth of ultrahigh reflectivity mirrors. However, a broadband prism cavity, first introduced by Lehmann and Rabinowitz in 1999, can have a spectral response ranging from the UV to IR.[3] This type of prism cavity can potentially measure spectral fingerprints of various species in different spectral regions. A new type of fiber loop (cavity) for detection of a small volume of liquid is discussed in Section 7.

3.2 Laser Sources

In principle, there is no restriction on the laser sources to be used for a ringdown system. Both pulsed lasers and CW lasers with wavelengths ranging from the ultraviolet to the IR can be used, given availability of ringdown mirrors coated for the appropriate wavelength region. Commonly employed pulsed lasers include pulsed dye lasers pumped by Nd : YAG or excimer lasers, or widely tunable optical parametric oscillator (OPO) lasers. CW ring dye lasers pumped by Ar^+ lasers and quantum cascade lasers (QCLs) have been also widely used for ringdown studies, as have mid-IR laser sources based on difference frequency generation (DFG) or Raman shifting techniques.[95] Inexpensive telecommunications diode lasers have been increasingly used in ringdown research and instrumentation because of low cost, small footprint, and high resolution. Broadband laser

sources have also been explored for ringdown studies. Engeln and Meijer injected a broadband dye laser pulse into a ringdown cavity and used a Fourier transform spectrometer to separate the frequency components of the pulse exiting the cavity.[96] Scherer also utilized a broadband laser beam for the development of a ringdown spectrometer.[97] Fiedler et al. measured the C–H overtone of liquid benzene using incoherent broadband CEAS.[98] Perhaps the most nonstandard laser system used for ringdown was reported by Engeln et al., who implemented CRDS in the IR using a free electron laser system to obtain a spectrum of a thin film of C_{60}.[99,100] Very recently, a broad-bandwidth optical frequency comb has been coherently coupled to a ringdown cavity for real-time, quantitative measurements of trace concentrations, transition strengths and linewidths, and population redistributions for molecules such as C_2H_2, O_2, H_2O, and NH_3.[66] The same group has demonstrated an improved frequency comb-based cavity ringdown spectroscopy system based on a mode-locked erbium-doped fiber laser source centered at 1.5 μm, resulting in an absorption sensitivity of $2 \times 10^{-8}\,cm^{-1}\,Hz^{-1/2}$ per detection channel for CO, NH_3, and C_2H_2 in a very large spectral bandwidth (1.45–1.65 μm).[67]

A critical issue when employing an absorption spectroscopy method such as CRDS is the laser linewidth. If the laser used in CRDS has a large linewidth, two measurement problems may arise. First, hyperfine structures of an optical transition or an isotopic shift cannot be captured owing to the lack of laser resolution. This is particularly true for atomic transitions and isotopic shift. Second, if the laser linewidth is too broad, accurate measurements for high-resolution spectroscopy and atomic absorption cannot be achieved (mostly, the overall absorption signal can be undermeasured). The effects of the laser linewidth on the accuracy of ringdown measurements have been experimentally observed and theoretically analyzed.[49–51,78,82,83,101–103] Even some pulsed lasers are suitable for moderate to high-resolution spectroscopy. For instance, a pulsed dye laser with double-grating configuration can have a linewidth of $0.08\,cm^{-1}$ at 590 nm (e.g. NarrowScan) and $0.03\,cm^{-1}$ at 570 nm (e.g. Sirah). A widely tunable OPO system (e.g. the MOPO-HF), can have a linewidth of $0.075\,cm^{-1}$. In contrast, CW lasers such as external cavity diode lasers (ECDL) or distributed feedback (DFB) diode lasers typically have a laser linewidth of kilohertz to megahertz levels ($1\,cm^{-1} = 30\,GHz$). Thus, as with other very high resolution absorption spectroscopy methods, CW laser CRDS methods are preferred for very high resolution studies.

Laser beam propagation behavior in a ringdown cavity depends on the cavity geometry and the nature of the medium in the cavity. For example, different gases filling the cavity have different refractive indices, thus generating different scattering losses. Refractive index variations or the existence of a large refraction gradient can increase ringdown baseline noise, create beam steering effects, or even prevent establishment of a ringdown event. For example, beam-steering effects have been observed in a ringdown cavity containing atmospheric-pressure plasma.[53,104] Severe beam deflections due to gas turbulence have been observed in plasma confined in tubing, preventing the establishment of a ringdown event.[48] A careful design of the ringdown cavity geometry or an optimized plasma gas flow pattern can minimize beam-steering effects.

3.3 Electronics

For pulsed-CRDS, the bandwidth of the laser is typically several times larger than the longitudinal mode spacing of the ringdown cavity. Therefore, the light on each laser pulse is coupled into the cavity and no additional electronic parts are required to achieve cavity excitation. When a narrow-linewidth diode laser is used as the light source, an additional electronic control is needed. The linewidth of a diode laser, e.g. an external cavity diode laser or a DFB diode laser, is much narrower than the cavity mode spacing, implying that the laser must be tuned into resonance with a cavity mode in order to excite the cavity. Engeln et al. first reported the use of an intensity-modulated, narrow-linewidth CW ring dye laser for CRDS.[105] This work utilized an unstabilized ringdown cavity and depended upon random fluctuations (such as variations in the cavity length due to vibration) to couple the laser into the cavity modes. To increase the coupling efficiency, a cavity with a dense mode structure was utilized. The phase shift of the intensity-modulated beam exiting the cavity was used to obtain a high-sensitivity spectrum. Later on, Romanini et al. described a method of actively coupling narrow-linewidth CW lasers (such as ring dye and diode lasers).[11,12] In these experiments, the length of the cavity was dithered by mounting one cavity mirror on a piezoelectric translator. By modulating the length of the cavity, the mode structure of the cavity was swept through the laser frequency. When the laser and cavity mode frequencies overlapped, light was efficiently injected into the cavity mode, rapidly increasing the intensity of the light in the cavity (i.e. the cavity was excited). The schematic of the method is shown in Figure 4. After these initial reports, several early studies using CW-CRDS were reported.[106–112]

CW-CRDS has matured into a standard ringdown technique. The methods of achieving the cavity excitation can be simply classified into three dominant categories[68–77]: (i) cavity length modulation to vary the cavity mode spacing, (ii) current modulation to vary the laser frequency, and (iii) a combination of the two

Figure 4 Simplified scheme of a CW CRDS setup. AOM, acousto-optic modulator. (Reprinted from ref. 81, with permission from Elsevier Science.)

methods. The first and the third methods have been almost abandoned owing to the complexity and the high cost of the required instrumentation. Currently, most instrumentation and research using CW-CRDS implements the current modulation scheme. In CW-CRDS, once the cavity is excited, shutoff of the excitation is needed to observe the ringdown decay behavior. Typically, an acousto-optical modulator (AOM) is used to deflect the laser beam away from the optical axis of the ringdown cavity to shut off the cavity buildup, thus allowing the ringdown waveform to be subsequently recorded.[68–77] This method requires an expensive AOM device and a trigger circuit to control the procedure. Another major disadvantage of this method includes a loss of laser power through the AOM. When a laser beam passes through the crystal of an AOM, losses in the observed laser power are typically 15–20%. This imposes a distinct disadvantage when a low-power DFB diode laser is used as the light source in a CW-CRDS system, since lower signal intensity means lower signal-to-noise ratio. Although many CW-CRDS-based research efforts are still using an AOM, CRDS-based commercial instruments have avoided implementing this device.[15]

An alternative approach to shut off the cavity excitation without using an AOM in CW-CRDS is controlling the laser current. Once the cavity is excited, the electrical signal from the detector is used to trigger a circuit, which drives the laser diode current below the threshold of the driving current. This procedure typically requires a specially designed electric circuit. This circuitry is a trivial engineering effort, but it is not readily available for research laboratories. Recently, a simple and effective method has been introduced to achieve cavity excitation and shutoff, using a standard off-the-shelf power combiner.[17,46] With this approach, the power combiner couples the output of a function generator with the output of a pulse generator to create a special voltage waveform to manipulate the diode laser current. This eliminates the need to use special electronic modulation circuits to achieve current modulation. This method has been successfully used in several ringdown research studies and applications.[17,46,57,58,62,64,113,114]

3.4 Data Analysis

Ringdown signals from a PMT or photodiode detector are typically digitized using a digital oscilloscope, transient digitizer, or fast A/D converter interfaced to a computer. Ringdown software is typically in-house developed, but is also commercially available. To determine the ringdown time, the resulting data is fitted as a single exponential function. In practice, averaging of multiple waveforms is often employed to smooth out shot-to-shot variations in the ringdown signals and improve the signal-to-noise ratio. Strictly speaking, such averaging is only valid if the waveforms are normalized in intensity. Alternatively, the ringdown time of each individual transient can be computed, followed by averaging a number of the computed time constants. Some early ringdown experiments used a dual-channel boxcar integrator to compare two different regions of the ringdown signal and extract a quantity proportional to the ringdown time.[115] This approach yielded results comparable to data fitting methods. However, the software method has the added advantage of providing a quick method of establishing if the ringdown waveform is a true single exponential decay. It is a simple matter to check the observed ringdown time in different regions of the transient to determine if the waveform is truly a single exponential function. In practice, e.g. if the difference in the ringdown times obtained by fitting different ranges in the decay curve is less than about 1%, fitting a single exponential decay is justified. Cavity misalignments, linewidth effects, and index of refraction variations in the cavity can all lead to nonexponential or multiple exponential waveforms.[116] Scherer et al. have considered, in some detail, the effect of various data-acquisition schemes and have concluded that while the temporal resolution of a digitizer system is important for determining the number of points sampled, the vertical resolution can be critical to the performance of a CRDS system.[70]

4 MOLECULAR APPLICATIONS OF CAVITY RINGDOWN

4.1 Introduction

At the time of this writing (2007), CRDS and its variants have yielded more than 700 publications worldwide

(based on a search using SciFinder). Of these publications, the majority are using CRDS in the area of molecular spectroscopy. Whether for fundamental molecular structure studies, or for applications in areas such as environmental monitoring, combustion studies, or plasma processing, CRDS has proven its capability to detect weak molecular absorptions or to measure trace molecular species. Molecular applications of CRDS continue to be one of the most active fields using CRDS. It also is the field that clearly demonstrates the extreme sensitivity of the cavity ringdown technique. A complete review of molecular spectroscopy using CRDS is beyond the scope of this article. However, reviews are available for further information concerning molecular spectroscopy using CRDS.[69,76,80,117–119]

4.2 Applications

4.2.1 Fundamental Molecular Spectroscopy

The measurement of a doubly forbidden transition in molecular oxygen by O'Keefe and Deacon provided the first demonstration of the ringdown technique.[1] Since then, molecular spectroscopists have taken advantage of the high sensitivity of CRDS and utilized CRDS in a wide variety of environments. Saykally and coworkers, in one of the earliest studies, demonstrated the usefulness of the technique in supersonic expansion applications by combining CRDS with a pulsed vaporization cluster source to record absorption spectra of Cu_2 and Cu_3 in a supersonic molecular beam.[120] This same group has continued the application of CRDS to cluster studies, eventually expanding their efforts to include a number of metal and mixed species clusters[121] as well as water[95] and methanol[122] clusters. The ultrasensitivity of CRDS also lends itself naturally to studies of molecular predissociation.[123–125] Figure 5 depicts a comparison of CRDS and LIF absorption spectra for HNO that clearly reveal features missing in the LIF spectrum due to predissociation of the molecular excited state.[89] Radical spectroscopy has also been the subject of ringdown studies, as demonstrated by early investigations of OH in flames[86,123,126,127] and the SH radical in an absorption cell.[125] Miller's group have observed weak electronic transitions of large alkoxy radicals in the NIR (1.2–1.3 μm) using CW-CRDS and the radicals are generated by laser photolysis of selected precursors. The absorption cross sections of these transitions are typically only on the order of $10^{-21}\,cm^{-2}$. With the high sensitivity of ringdown spectroscopy, abundant rotational and vibrational data have been obtained for methyl peroxy (CH_3O_2),[128] trifluoromethyl peroxy (CF_3O_2),[129] acetyl peroxy ($CH_3C(O)O_2$),[130] propyl peroxy ($C_3H_7O_2$),[131] phenyl peroxy ($C_6H_5O_2$),[132] and ethyl peroxy ($C_2H_5O_2$)[133] radicals, whose spectra in UV or visible (VIS) are typically overlapped so that little spectroscopic information can be obtained. An early demonstration of the extreme sensitivity of

Figure 5 Cavity ringdown spectra (a) and LIF (b) of HNO A^1A''–X^1A' transition (100)-(000) $K' = 4$-$K'' = 3$ and (020)-(000) $K' = 5$-$K'' = 4$ subbands. Line assignments are shown by the combs above the spectra. Much of the structure present in the CRDS spectrum is absent in the LIF spectrum because of predissociation of the A^1A'' state. (From ref. 89. Reproduced by permission of the American Institute of Physics.)

the technique was the observation of weak overtone transitions. Romanini and Lehmann used cavity ringdown to investigate very weak overtone transitions in HCN.[80] In so doing, they demonstrated per pass absorbance detection limits on the order of 10^{-7}. In addition to molecular structure studies, CRDS has also been used in kinetics experiments.[134–137] By monitoring the temporal densities of chemical reaction products and/or reactants, reaction kinetic constants and reaction mechanisms are investigated.[134–138] It should be noted that fundamental molecular spectroscopic studies using CRDS have been extended beyond the few areas briefly mentioned above and the publications continue to increase.

4.2.2 *Combustion Flame Chemistry and Plasma Diagnostics*

A consistent challenge facing the combustion community has been to measure concentrations for various reactant, intermediate, and product molecules as a function of flame conditions and position within the flame. Direct sampling from such an environment is inaccurate, particularly for radicals, since reactions continue to proceed as the gas is sampled and transferred to an analysis system. The distribution of species in the gas sample may bear little resemblance to the original gas at the sampling position in the flame. Thus, accurate in situ methods for combustion analysis have long been desired. However, the hostile environment and intense background emission of such systems can frustrate attempts to use traditional optical analytical methods for in situ measurements. Emission spectroscopy is only capable of detecting excited state species, greatly limiting its usefulness for diagnostic purposes. Other techniques such as LIF,[117] coherent anti-Stokes Raman spectroscopy (CARS),[139] and degenerate four-wave mixing (DFWM)[117] have all yielded excellent results, but can be hampered by difficulties in calibrating for absolute measurements. A highly sensitive absorption spectroscopy technique, such as CRDS, provides an ideal complement to other analytical diagnostic methods.

The use of CRDS for flame analysis was first reported in 1994 by Meijer et al.[86] This work measured the absolute absorbance for OH radicals (near 308 nm) generated in a Bunsen burner flame. Since that time, a number of CRDS studies have investigated radical concentrations in flames including HCO,[140] CH_3,[117] CH_2,[141] and CH.[142] Also, studies have continued to investigate the behavior of the OH radical under various combustion conditions.[82,86,126,127,143] Mercier et al. carried out extensive measurements comparing CRDS, direct absorption spectroscopy, and LIF for quantitative analysis of OH radical concentrations and spatial profiles in flames.[143] Zalicki et al. demonstrated the detection of methyl radicals generated when a mixture of methane and hydrogen flowed over a heated filament.[144] Absorbances and spatial profiles were measured for methyl radical column densities far below those required for standard multipass absorption spectroscopy. Schocker et al. measured absolute concentrations of OH, HCO, and CH_2 in a propene flame near the soot-formation limit.[145] Both temperature and radical concentration profiles were discussed in that study.

Direct applications of CRDS for detection of species in a plasma have been somewhat more limited in number. However, due to the dual facts that plasma technology is very important in semiconductor industries, material processing, and analytical applications, and that CRDS has the unique capability of measuring absolute concentration of chemical species in plasmas, this number has grown rapidly during the last few years. In a very early development, O'Keefe used the technique to measure N_2^+ ions in a glow discharge.[146] Kotterer, Conceicao, and Maier, studied N_2^+ ions in a hollow cathode source.[147] Negative ion concentrations were reported by Quandt, et al., who used CRDS for quantitative measurements of H^- ions in a magnetic multipole source.[148,149] In this case, rather than traditional absorption, the optical losses associated with the electron photodetachment process were monitored. Later, Romanini et al. investigated the spectra of naphthalene cations created in a slit jet/electronic discharge source.[150] This work resulted in the first gas-phase electronic spectrum for an ionized polycyclic aromatic hydrocarbon. Wang et al.[151] measured OH density profiles in an atmospheric argon inductively coupled plasma (ICP) using a pulsed-CRDS system. They also measured the density of SrOH radicals in the plasma using an external cavity diode laser at 679 nm.[46] Recently, Oever et al. measured NH and NH_2 radicals using CRDS in an extensive characterization of the Ar-NH_3 expanding thermal plasma source, which is widely used for silicon nitride deposition in industrial processes.[152]

Of perhaps the most practical interest for plasma analysis is the use of CRDS for measurements in reactive plasmas for semiconductor growth and plasmas employed in analytical applications. Monitoring the species present during semiconductor growth can provide important information for controlling the growth process, detecting impurities, and optimizing plasma operation conditions. In related research, Campargue et al. used CRDS to determine the concentrations of SiH_2 radicals in a dc discharge plasma containing a mixture of silane and argon.[153] Booth, et al. have employed CRDS to measure radicals and etch products in a capacitively coupled radio-frequency plasma.[154] SiF_2 was measured as a product of

the etch process when a silicon wafer was placed in the system.

Interest in plasma diagnostics using CRDS continues to increase. Key plasma parameters, which include electron density and plasma temperatures, can be characterized through ringdown measurement of species in the plasma. Owing to the large gradients of plasma temperature and heterogeneity of plasmas, plasma temperature profile and electron density profile are spatially dependent. Linewidth broadening mechanisms in plasma, including Doppler broadening, Stark broadening, and collisional broadening, are complicated.[155] Which mechanism is dominant under a particular plasma condition is dependent on the plasma temperature(s), electron density, location in the plasma, etc. Detailed discussions on linewidth broadening mechanisms under plasma conditions can be found elsewhere.[20,155–157] A recent review on plasma diagnostics using laser techniques including CRDS was given by Ganguly et al.[158]

Yarlin et al. measured the spatial profiles of N_2^+ concentration in an atmospheric pressure N glow discharge by CRDS.[53] They also measured the temporally resolved N_2^+ concentration in a pulsed atmospheric pressure N plasma.[104] Wang et al.[20] measured concentration and lineshapes of atomic lead transitions at 283 nm in different vertical and lateral positions of an atmospheric argon ICP. Fitting a lineshape into a Voigt lineshape yields Doppler and Lorentzian components, from which plasma gas kinetic temperature and electron density were estimated. In this way, a plasma gas kinetic temperature profile and electron density profile in the plasma were mapped out. Using similar method, the lineshapes of the rotational transition line $S_{21}(1)$ in the OH $A^2\sum^+ - X^2\prod$ (0–0) band were measured and plasma kinetic temperature profile was also derived.[151] Through simultaneous measurements of ringdown absorption spectra and emission spectra of OH radicals in the plasma, the local thermoequilibrium approximation (LTE) was evaluated.[151] One disadvantage of the ringdown measurement in a circular plasma is the line-of-sight measurement, which yields an integrated measurement along the laser beam path. Although Abel inversion can convert the line-of-sight measurements to radial distributions, the conversion process requires a relatively large number of data points in order to achieve an accurate measurement. However, practically, this line-of-sight measurement gives an acceptable measurement uncertainty of plasma gas temperature and electron density, e.g. 10–15%, for plasma diagnostics.[20,151,156]

Another relatively new CRDS-related application is sputtering plasma monitoring. Ion beam sputtering plasma is created when an energetic ion beam bombards the surface of a metallic target. In the process, chemical species, such as small molecules, free radicals, and atoms are sputtered from the target and form a sputtering plasma. Real-time in situ monitoring of sputter erosion is important in the operation of electric propulsion devices[159] and the development of nuclear magnetic fusion.[160] Compared with other optical techniques that are used for sputtering monitoring, such as optical emission spectrometry (OES),[161,162] LIF,[163,164] and resonance-enhanced multiphoton ionization time-of-flight mass spectrometry (REMPI-TOF-MS),[165,166] CRDS is advantageous in the areas of real-time response, high sensitivity, and absolute measurement of number densities. In an earlier work,[35] CRDS was used to measure the number density of silicon (Si) atoms generated by radio discharge plasma sputtering. Recently, CRDS has been used to study sputter erosion of a metallic target.[36,37] In those studies, the ion beam source and the target were housed in a vacuum chamber with a background pressure of 10^{-6}–10^{-7} Torr. Energetic argon ions bombarded a metallic target and elements were generated around the surface of the target. CRDS with a UV laser beam (375–400 nm) from an OPO system was used to detect the densities of the sputtered elements, such as ion (Fe), aluminum (Al), molybdenum (Mo), and titanium (Ti). Detection sensitivities of these elements were in the 10^6–10^7 atoms/cm^3 levels, which were lower than typical number densities of sputtered particles in electric propulsion devices. The analytical applications of CRDS associated with a plasma source are discussed in Section 5.

4.2.3 *Environmental Applications*

Trace chemical detection in environmental applications is another important area in which CRDS is playing an increasingly important role. Soon after the publication of the original CRDS paper, O'Keefe and Lee reported the detection of NO_2 at subpart per billion levels using CRDS.[87] Brown,[167] in 2002, measured NO_3 using narrowband pulsed dye lasers and Ball,[168] in 2003, also measured NO_3 using a broadband pulsed dye laser. Mazurenka et al.[169] demonstrated fast Fourier transform cavity ringdown spectroscopy (FFT-CRDS) for detection of NO_2 with a detection sensitivity of 150 ppt. Simpson developed a CW-CRDS spectrometer to monitor NO_3 and N_2O_5 at 662 nm with a detection limit of 2.4 ppt for N_2O_5 in a 25-s average.[170] Meijer's research group demonstrated the detection of NH_3 at the 10 ppb level, and a detection limit of less than 1 ppt was reported for mercury in room air.[101]

Results such as the above have sparked a keen interest in the use of CRDS for difficult environmental monitoring problems. Vasudev et al. explored the use of CRDS for applications in monitoring offgases from

thermal treatment systems such as hazardous waste incinerators.[29] The real-time detection of low vapor pressure chlorinated organic species, and in particular species such as the dioxins and furans, is highly desirable and extremely difficult. Other ultrasensitive techniques such as LIF and REMPI suffer a reduction in sensitivity for such species due to a strong intersystem crossing between excited state singlet and triplet levels. CRDS, being an absorption method, is much less affected by the fate of the excited state and should possess the sensitivity to implement such measurements. The Orr-Ewing research group reported measurements of trace volatile organic compounds (VOCs), such as ethyne, ethene, 1,3-butadiene, 1-butadiene, 2-methylpropene using two DFB lasers and one ECDL in the NIR.[171] The detection limits of these VOCs are in the subparts per billion to a few parts per million levels. The same group combined a preconcentration technique typically used in gas chromatography (GC) with CW-CRDS and demonstrated the capability of measuring ethane in urban air at a mixture ratio level of 6 ppb.[172] Winstead et al. measured absorption cross sections of the first C−H overtone of several VOCs, such as benzene, toluene, chlorobenzene, and dichlorobenzene using an NIR external cavity diode lasers cavity ringdown spectroscopy (ECDL-CRDS) system.[173,174] More recently, Cias reported measurement of absorption cross sections of the first C−H overtone of 1,3-butadiene, 2-methyl-1,3-butadiene (isoprene), and 2,3-dimethyl-1,3-butadiene using CW-CRDS at 1650 nm.[113] The overlap of the overtone spectra of many large VOCs challenges the spectral selectivity. One possible solution is to measure the fundamental transition in the middle IR using an IR laser source.

With the increasing concern about global warming and more stringent standards for reduction of the greenhouse gas (CO_2 and CH_4) emissions, interest in measurement and monitoring of atmospheric greenhouse gases remains high. CRDS is receiving growing recognition of being able to play an important role in this field. For example, the use of CRDS as an intelligent control system for advanced coal combustion system to monitor typical emission gases (e.g. CO_2, CO, NO, NO_2, N_2O, SO_2) together with total mercury.[175] Early measurements of important atmospheric/environmental molecules, such as CO_2, NH_3, CH_4, and HCHO were performed in a laboratory low-pressure system. Fawcett reported the first measurement of tropospheric methane using CW-CRDS at 1650 nm with a detection limit of 52 ppb.[31] Awtry and Miller developed sensors for air quality monitoring in spacecraft capsules using CW-CRDS at 1550 nm.[32] They demonstrated detection limits for CO and CO_2 at single digit parts per million levels and for NH_3, HCN, and C_2H_2 at a few parts per billion levels. Similar atmospheric molecules, such as, CO, CH_4, NH_3, and C_2H_2, were also measured by CRDS's variant, CEAS or ICOS in the early studies.[176]

One of the important applications in greenhouse gas monitoring is to identify the source of greenhouse gases. The isotopic abundance ratio of C13 to C12 is a reliable signature for source identification. Diode laser CRDS offers a high-resolution and high-sensitivity measurement of the C13 isotope. Crosson et al. developed a sensitive NIR CW-CRDS system for measurement of the isotopic ratio of C13 to C12 in the range of 6261–6264 cm^{-1}.[54] The low-pressure measurement at 70 Torr yields a high accuracy of 0.22 per mil, which is comparable with the results obtained using isotope ratio mass spectroscopy (IRMS). Castrillo et al. also developed a spectrometer for measurement of C13/C12 in CO_2 at 2 μm.[177] The spectrometer has an accuracy of 0.5 per mil for C13. Wang et al. recently developed a battery-powered, remotely accessible, portable ringdown spectrometer for detection of CO_2, CH_4, and C13.[114] The instrument is being tested at the US Department of Energy carbon sequestration sites. Two laser diodes at 1650 and 1596 nm were multiplexed through a fiber splitter for simultaneous measurements of CO_2, CH_4, and C13 in two different wavelength regions. Ding et al. combined 31 DFB laser diodes to measure absorption spectra of $^{13}CO_2$ in the 6130–6750 cm^{-1} and numerous new transitions were added to the CO_2 spectral database.[178] ICOS and DFG-based IR absorption have also been used to measure C13 isotope in the IR spectral regions. Owing to the larger line strength of the fundamental transition in the IR,[179] these methods have also achieved high sensitivity.

Recently, CRDS has been employed for studies of optical extinction by aerosol particles. CRDS measures the total optical extinction resulting from the sum of scattering and absorption losses.[90,180–182] The losses depend on the number density, size distribution, and index of refraction of the particles. Different laser sources including UV and NIR laser have been used to measure extinction caused by particles such as nonabsorbing polymer beads and absorbing smoke particles. Thompson et al. investigated the extinction coefficient of ambient air as a sensitive indicator of micrometer-sized airborne particles through CRDS at two wavelengths.[183] Very recently, Timothy et al. demonstrated the measurement of single aerosol particle extinction using optical feedback cavity ringdown spectroscopy (OF-CRDS) method.[184,185] The OF-CRDS technique allows high repetition rate measurement up to 1.25 KHz, which allows multiple measurements of the aerosol extinction of a single particle.

5 ATOMIC APPLICATIONS OF CAVITY RINGDOWN SPECTROSCOPY

5.1 Introduction

Application of CRDS for atomic absorption measurements was first reported by Jongma et al.[101] who reported measurement of elemental mercury in air using CRDS with a detection limit of less than 1 ppt. Subsequently, Miller and Winstead[18] demonstrated the first P-CRDS measurements for analytical atomic spectrometry by introducing an ICP source into a CRDS system and measuring lead concentrations using a pulsed laser at 283 nm. In analytical P-CRDS, the plasma is used as an atomization source to generate atoms and ions and CRDS serves as a sensitive detector. Several publications have reported continuing development of analytical P-CRDS. P-CRDS has been demonstrated to be a powerful technique not only for high-sensitivity analysis of a variety of elements but also for trace isotopic measurements. During the last 10 years, several elements and isotopes have been measured using the P-CRDS technique. The use of different plasma and laser sources has been demonstrated and detection limits comparable to inductively coupled plasma mass spectrometry (ICP-MS) have been reported. A review of P-CRDS for elemental and isotopic measurements has recently been published.[21,77] This section incorporates an update on the development of the P-CRDS technique since the last review. Emphasis is placed on the improvement of the P-CRDS technique and isotopic measurements.

5.2 Principle of Plasma Cavity Ringdown Spectroscopy

P-CRDS follows the same measurement principles as CRDS. Including losses resulting from the high-temperature atmospheric plasma and the open-air cavity, the observed ringdown time in a P-CRDS system can be expressed as[20] in Equation (11):

$$\tau = \frac{d}{c(1 - R + \beta_{\text{plasma}} l_s + \beta_{\text{air}}(d - l_s) + \text{absorbance})} \tag{11}$$

where d is the distance between the two cavity mirrors, R is the mirror reflectivity, β_{plasma} and β_{air} are the broadband scattering coefficients in the plasma and open-air cavity, respectively, c is the speed of light, and l_s is the laser beam path length through the plasma. In practice, because the scattering coefficients vary slowly over the bandwidth of the cavity mirrors, such losses are simply incorporated into an effective reflectivity R_{eff}. The ringdown time equation can be expressed as in Equation (12):

$$\tau = \frac{d}{c(1 - R_{\text{eff}} + \text{absorbance})} \tag{12}$$

where the absorbance is defined in Equation (5). In the case of plasmas, the density of absorbers is position dependent. As a result of the complicated linewidth broadening mechanisms under atmospheric plasma conditions, the lineshape of the absorption line is of a Voigt profile and the absorption cross section can be represented by Equation (13)[52,186]:

$$\sigma_{ij}(\nu) = \frac{g_j}{g_i} \frac{\lambda^4}{4\pi^2 c} \frac{A_{ji}}{\Delta\lambda_D} V(a, 0) \sqrt{(\pi \ln 2)} \tag{13}$$

where g_j and g_i are the upper and lower state degeneracies respectively, λ is the transition wavelength, c is the speed of light, and A_{ji} is the spontaneous emission transition rate (also known as *transition strength* or *transition Einstein A coefficient*). For most atomic/ionic transitions, these parameters are well documented in the literature. $\Delta\lambda_D$ is the Gaussian component of the broadened linewidth due to Doppler broadening. $V(a, 0)$ is the Voigt function determined by linewidth broadening mechanisms and the a parameter is determined by the ratio of Lorentzian and Gaussian components.[157] In practice, the measured lineshape is typically the spatially averaged and integrated lineshape along the particular line of sight; therefore, an averaged value of the cross section is obtained.

Using the experimental lineshape data to determine the average cross section allows for the measurement of the average density of atoms or ions in the lower state of the transition to be probed. For the purpose of plasma diagnostics, such as measuring the distribution profile of electron density, gas kinetic temperature, and analyte/species density, the line-of-sight measurement may generate a large deviation[20,151,156,187,188]; Abel inversion may be used to convert the lateral measurements to the radial distributions.[20,189] However, for analytical applications in which the detection sensitivity is the quantity of concern, the line-of-sight measurement is appropriate.

5.3 Plasma Cavity Ringdown Spectroscopy for Elemental Measurements

5.3.1 Inductively Coupled Plasma Cavity Ringdown Spectroscopy

The ICP is a robust plasma source and has widely been used as an excitation source for emission spectroscopy study of analytes. Miller and Winstead first coupled an inductively coupled plasma cavity ringdown spectroscopy (ICP-CRDS) to demonstrate general analytical atomic applications of CRDS.[18] The ICP-CRDS system was initially constructed using a pulsed laser source and an ICP source to demonstrate the technical feasibility

Figure 6 An ICPCRDS wavelength scan recorded 70 mm above the ICP load coil for blank and 100-ppm Pb solutions. (From ref. 18. Reproduced by permission of The Royal Society of Chemistry.)

and to explore the detection sensitivity of the system. A standard lead (Pb) solution was diluted at different concentrations and injected into an ultrasonic nebulizer to generate sample gas mist, which was carried by argon into an atmospheric-pressure argon ICP. The plasma used a standard ICP quartz torch coupled with a 27.12 MHz ICP power supply.[18] The detection limit of Pb at 283-nm transition line was in the microgram per microliter level. Figure 6 shows the first elemental measurement of Pb using the ICP-CRDS technique.[18]

Following the initial introduction of ICP-CRDS,[18] extensive P-CRDS optimization has been investigated by optimizing each operating parameter individually and, subsequently, in combination with the other parameters. The detection limit of the system has been improved to 300 pg mL^{-1} for Pb,[20] which is several orders of magnitude lower than the initially demonstrated detection limit. This detection limit of Pb is much better than the detection limit obtained by ICP-OES, slightly better than inductively coupled plasma laser-induced fluorescence (ICP-LIF), and comparable with that from ICP-MS.[20] It should be noted that the results in that work were obtained with a modified ICP plasma torch, which allowed the ICP to operate at an extremely low power of 200 W. With this modified ICP-CRDS system, Pb, Hg, and Mn were also measured and the detection limits were in the nanogram per microliter to picogram per microliter levels.[20–23,46–48]

5.3.2 Microwave Induced Plasma Cavity Ringdown Spectroscopy

The measurement of Pb by the low-power ICP-CRDS system inspired the exploration into different plasma sources, especially those capable of operating at low plasma powers. Microwave induced plasma (MIP) is a powerful alternative source for atomic excitation in elemental analysis and has been extensively used in analytical atomic spectrometry.[190,191] Compared with other types of plasma sources, an MIP offers some attractive characteristics, such as low power, low gas flow rates, and low cost for instrumentation and maintenance, making it a desirable source for absorption measurements.[192] Duan et al. have investigated coupling an microwave induced plasma cavity ringdown spectroscopy (MIP-CRDS).[23] In that study, lead was chosen as a typical element for the system demonstration so that the results could be directly compared to those from an ICP-CRDS system. A detection limit of 0.8 ng mL^{-1} for Pb was obtained in that initial feasibility study.

Physically, an MIP-CRDS system has a smaller instrument footprint, lower weight, and lower operating costs than an ICP-CRDS system. MIP-CRDS also has one unique analytical merit that is not offered by ICP-CRDS: the baseline noise, σ/τ, is not affected by the presence of the plasma. In the ICP-CRDS system, the ringdown baseline noise was three to four times larger when the plasma was on than when the plasma was off.[20] However, it was found that the MIP used in the MIP-CRDS system did not generate additional baseline noise to the system. Whether the plasma was on or off had no effect on the baseline noise, which was the same at about 0.3% in both on and off conditions. These results indicate that the baseline noise is improved by a factor of 3–4 by using an MIP in place of an ICP. It should be noted that in addition to the plasma associated baseline noise, the laser beam position in the plasma and the plasma gas flow rates also influence the detection sensitivity. Very recently, a low-power miniature microwave plasma torch (MPT) has been employed with CRDS to measure elemental mercury with a plasma operating power of only 15 W.[48]

Diode lasers have also been employed for atomic spectrometry in P-CRDS. An external cavity diode laser operating at 679 nm was used to measure strontium (Sr).[46] In that study, diluted standard solutions of strontium (Sr) were introduced into the plasma by an in-house fabricated sampling device combined with an ultrasonic nebulizer. SrOH radicals[193–195] were generated in the plasma, and the detection of Sr was made by measuring SrOH radicals in the plasma. This study demonstrated the potential of P-CRDS instrumentation using a compact CW laser source.

5.4 Plasma Cavity Ringdown Spectroscopy for Isotopic Measurements

Isotopic analysis is an important field in analytic atomic spectroscopy. For example, in the field of environmental monitoring, isotopic abundance is often

used as spectral fingerprint to study transform, fate, and chemical processes of analytes. Most isotopic analyses are performed by a laboratory ICP-MS system. However, these systems require tedious sample preparation and sophisticated operation and maintenance, and they are not portable for real-time, on-site analysis. The ICP-MS system can also suffer from isobaric effects. For instance, an ICP-MS system cannot readily distinguish ^{238}U from ^{238}Pu. In early studies, an ICP was combined with the LIF technique (ICP-LIF) to measure U isotopes at 286 nm. Uranium has a strong transition at 286 nm and the isotopic shift is of 0.6 cm^{-1}.[196] With the ICP-LIF technique, the measurements of ^{235}U and ^{238}U in different matrices were conducted with a detection limit of 1 $\mu g\,mL^{-1}$.[122] LIF combined with laser ablation was also implemented to measure isotope ratios of ^{235}U transition at 682.67 nm and ^{238}U at 682.69 nm under low-pressure conditions and achieved a detection limit of 0.6 $\mu g\,mL^{-1}$.[197]

The ICP-CRDS system was applied to isotopic measurements of uranium at three different wavelengths: 286, 358, and 409 nm.[21] The U transitions at 286 and 409 nm are ionic transitions, but the U transition at 358 nm is an atomic transition. With the optimized ICP-CRDS system, the detection limits of U and its isotopes were in the nanogram per microliter levels.[21] Figure 7 shows typical isotopic measurements of uranium with a 50%/50% mixture of ^{235}U and ^{238}U. ^{235}U existing in ^{238}U with the natural abundance ratio of 0.79% was also measured.[21] This research demonstrated high-resolution isotopic analysis with high detection sensitivity using the P-CRDS technique.

The Hg transition at 254 nm has seven stable isotopic components with well-documented abundance ratios.[198–200] An early ICP-CRDS system was used

Figure 7 Uranium isotopes at 286 nm measured by using ICP-CRDS. *(Appl. Spectrosc.*, 2003, **57**, 1167–1172 by Wang et al., Figure 3 on page 1169.)

to measure a low-resolution hyperfine contour of this transition.[201] The isotopic abundance ratio of the stable isotopic components was barely quantified. The linewidth broadening under the high-temperature ICP ultimately limited the instrument's capability of measuring high-resolution hyperfine structures of the Hg transition at 254 nm. With the lower plasma temperature in the MIP, the Hg hyperfine structures were more clearly resolved.[47] With a newly developed tube-shaped MIP torch (MPT), which allowed the plasma to operate at powers as low as 15 W, high-resolution Hg hyperfine structures were also recorded as shown in Figure 8.[48]

When the three different plasma sources (ICP, MIP, and MPT) were applied to the P-CRDS system for Hg measurements, interesting spectral background information was obtained.[47] With the ICP-CRDS system, no significant spectral interference was observed. However,

Figure 8 Hyperfine structures of mercury transition at 254 nm measured by using MIP-CRDS. (Reprinted with permission from ref. 48. © 2005 American Chemical Society.)

with the MIP-CRDS system, a strong OH transition located at 253.65 nm generated a significant spectral interference with the absorption peak of Hg at 254 nm. This OH transition was attributed to the overlap of two broadened rovibrational transitions $R_{21}(21)$ and $P_1(15)$ of the OH A-X (3–0) band.[47] The spectral interference limited the detection sensitivity of the Hg. This OH interference observed when using the MIP was remarkably eliminated by using a tube-shaped MIP torch, which was constructed in a long quartz tube.[48] The disappearance of the OH-spectral interference in the microwave plasma torch cavity ringdown spectroscopy (MPT-CRDS) is partially due to the fact that the MPT has a very small cross-sectional area at the end of the tube interacting with the plasma surroundings.

5.5 Electrothermal Atomization Cavity Ringdown Spectroscopy

An atomization technique that would also appear to lend itself well to CRDS is electrothermal atomization (ETA). As with other conventional absorption techniques, electrothermal atomization atomic absorption spectroscopy (ETA-AAS) attempts to measure a small change in the total transmitted intensity of a light source through an absorbing medium. For a commercial ETA-AAS system, the typical absorbance detection may approach 10^{-4} at best. Comparing this value to the 10^{-5}–10^{-8} absorbance for CRDS, the potential of coupling the two techniques together is obvious. An estimate of potential electrothermal atomization cavity ringdown spectroscopy (ETA-CRDS) performance can be obtained by comparison with modern commercial ETA-AAS systems, where a Pb characteristic mass of approximately 5 pg is typical.[202] The characteristic mass implies an absorbance of 4.4×10^{-3}. By again assuming an approximately 10^{-5} absorbance detection and scaling the mass linearly with the absorbance, the CRDS detection limit is expected to be in tens of femtogram range.

Winstead, Miller, et al. successfully demonstrated the first use of ETA-CRDS for measurement of elemental mercury.[19] The introduction of the graphite furnace within the cavity requires simply that the furnace be stable and that the laser beam pass through the center of the graphite tube. In this initial study, the furnace housing windows were removed to reduce optical loss and small holes at the ends of the graphite furnace were introduced to pass the laser beam. Some evidence of the presence of oxygen within the system, especially at high temperatures, was noted. Mounting the mirrors directly on the furnace housing with an argon gas purge would eliminate this problem. Once again, the primary loss mechanisms governing the decay time of the cavity are mirror reflectivity losses, atomic absorption in the graphite furnace, plus Rayleigh scattering from air in the cavity. As CRDS is based on measuring an intensity decay rate, it discriminates effectively against the furnace blackbody radiation.

Owing to the transient nature of the atomic absorption signal in a graphite furnace, a fast, high-resolution data-acquisition system is required so that integrated absorbance values can be obtained for each atomization cycle. The PMT signal was digitized by a 12-bit, 100 MHz sample rate analog-to-digital converter with the timing for data acquisition determined by the software controlling the graphite furnace. Eighty waveforms were saved over a period of 4 s for each atomization cycle, from which the peak and integrated absorbance values were determined. Figure 9 depicts the response of $1/\tau$ for lead (283 nm) as a function of the data-acquisition time following the start of the atomization step. Using a system having effective mirror reflectivity of 99.86% and a baseline ringdown time variation of 2–3% yielded detection limits of 1 and 2.7 pg for lead and mercury, respectively.[19] These results are an order of magnitude better for mercury, but only slightly better for lead, than the typical detection limit obtained by ETA-AAS.[202] Additional enhancements can come from further optimization of the laser linewidth, increased cavity stability during the furnace atomization sequence, a faster duty cycle for data acquisition, and optimization of the furnace operation itself. For example, the atomization process within a graphite furnace is generally complete in under 1 s while an Nd : YAG laser repetition rate is only 10–100 Hz (20 Hz in the example above). This implies that significant benefit would accrue from the use of higher repetition rate lasers.

Recent work has focused on developing a CRDS mercury emission monitor. Such an instrument requires, among other things, a determination and elimination of any background absorptions or interferences caused by other constituents of flue gas emissions from coal-fired power plants. For example, it is well known that sulfur dioxide (SO_2) absorbs UV radiation in the same spectral region as mercury (253 nm) resulting in a significant problem for most mercury detection equipment. Indeed, presently used commercial Continuous Emission Monitors (CEMs) based on atomic emission, atomic fluorescence, or atomic absorption require the removal of SO_2, and other flue gas constituents, before an accurate determination of the mercury concentration can be made. Recent research using CRDS to monitor mercury emissions from coal-powered utilities used thermal decomposition to convert mercury compounds to elemental mercury to provide a total mercury measurement. It has been noted[20,47,201] that the presence of isotopic structure during a scan of the mercury 253-nm line raised the possibility of separating these two absorbance components. Using a diode-seeded alexandrite laser, this possibility was confirmed. That is, the characteristic Hg isotopic peaks could be used to provide a unique identifier for mercury in exhaust gases.[175,203] For example, using a gas mixture containing 1.2 ppb mercury and 2175 ppm SO_2 respectively, the five mercury peaks obtained using CRDS are easily resolved above the SO_2 background absorption, and it was possible to accurately extract both the Hg and SO_2 concentrations. In 2004, Miller performed a field test of this instrument at a Department of Energy (DOE) Pittsburgh facility.[175] The results obtained support the conclusion that CRDS is a very promising technique for monitoring total mercury. However, practical success of such instruments dependent on the development of compact and low-cost UV laser sources remains a challenge.

6 MEDICAL APPLICATION OF CRDS–BREATH ANALYSIS

6.1 Introduction

Normal human breath contains hundreds of VOCs in very low concentrations ranging from part per trillion to part per billion levels.[204] Some VOCs have been identified as biomarkers for specific diseases. For instance, alkanes are present in the case of lung cancer and formaldehyde in the case of breast cancer[205]; the presence of isoprene in human breath is related to blood cholesterol levels[206]; and patients with Type 1 diabetes (T1D) or on ketogenic diets have acetone in their breath.[207,208] Such knowledge suggests that breath analysis is useful for human disease diagnostics. However, owing to the low concentration and the large number of chemical species in exhaled breath, breath analysis requires highly sensitive and selective instruments to detect and identify the abnormal concentrations of specific biomarkers. One major instrument presently employed for breath VOCs analysis is gas chromatograph mass spectrometry (GC-MS).[209–213]

Owing to its unique features of high sensitivity and absolute measurement of gas concentration of species of interest, CRDS has been well recognized to be an excellent technique for real-time, noninvasive breath gas analysis. However, its application in breath gas analysis is still in its infancy. At the time of this article being written, there have been only a few publications reporting on breath analysis using CRDS[54,55,214] or using its variant – cavity leak-out spectroscopy (CALOS),[215–217]/ICOS.[218] However, the application of CRDS to breath analysis is expected to increase. Recent reviews on breath analysis are available.[56,219–221]

6.2 Breath Analysis

Monitoring of C13 isotopic ratio in breath gas can help diagnose the presence of bacterium *Helicobacter pylori*. Crosson et al.[54] measured carbon isotopic ratio of C13 to C12 in breath CO_2 using CW-CRDS in the NIR spectral region. For the original form of CRDS, this is likely the first report on medical application of CRDS. They used a DFB laser diode at 1657 nm and performed measurements at low pressure (70 Torr). The detection limit of δ C13 was 0.22 per mil and was compared with the results from a commercial isotopic spectrometer. Wahl et al.[222] reported recent progress on C13 isotope measurement using CW-CRDS, also in the NIR spectral region. Using a preconcentration process, they demonstrated the capability of measuring the C13 isotope in both high-concentration CO_2 (e.g. 4%) and low-concentration CO_2 (e.g. 350 ppm) with an accuracy of 0.2 per mil. Wang et al.[55] developed a compact ringdown device using a miniature 266-nm laser source for detection of acetone, a biomarker of diabetes in breath. The instrument has sufficient detection sensitivity to detect abnormal breath acetone. The instrument was further improved and evaluated in the areas of detection sensitivity and response time with acetone sample solutions.[223] They demonstrated that a single measurement of acetone can be done within 46 s using the prototype acetone breath analyzer. The detection limit of acetone was 0.49 ppm. Very recently, this acetone detection device has been reconfigured to be a portable unit and tested with 59 human subjects including type 1 and type 2 diabetic outpatients in a clinic.[224]

Instead of using CRDS, several studies on breath biomarkers using the CRDS variants CALOS, CEAS,

and ICOS, have been reported. Ethane and pentane in human breath gas are biomarkers for lipid peroxidation and oxidative damage of human tissue. Murtz et al.[215] first reported on the measurement of breath ethane and pentane using mid-IR CALOS. The detection limit of ethane is 100 ppt. The same group also demonstrated on-line monitoring of breath ethane using the CALOS at 3.3 μm,[216] which was generated by periodically poled lithium niobate (PPLN) pumped by an Nd:YAG laser. The detection sensitivity was later improved to 6 ppt by using a mid-IR OPO laser source, and multiple breath compounds in human breath gas such as methane, ethane, and water were simultaneously analyzed.[217] Halmer et al.[225] recently reported on a mid-IR CALOS spectrometer and demonstrated the detection of breath carbonyl sulfide (OCS) with a detection limit of 7 ppt. In that study, multiple species in a single breath, such as ethane, CO_2, and O_2 were simultaneously measured. The temporal resolution of the breath-ethane concentration was clearly resolved within the first 500 s. In comparison, the GC method used in that research required 30–60 min for a measurement and the CALOS needed less than 1 min, as shown in Figure 10. The method demonstrated in this work is expected to be extended to the analysis of other small molecules such as NO, CO, OCS, and other hydrocarbons. Bakhirkin et al.[226] have demonstrated an ICOS-based system using a QCL at 5.2 μm to measure breath NO for diagnostics of lung disease. Very recently, McCurdy et al. have demonstrated real-time simultaneous measurement of NO and CO_2 in a single breath cycle using ICOS with two QCLs operating at 5.45 and 5.22 μm. They demonstrated the detection limit of NO at 0.4 ppb with a 1 s integration time.[227]

The Ye research group has recently introduced a novel cavity-based technique for analysis of multiple breath species in a broad spectral range. They reported human breath analysis using an optical frequency comb fiber laser combined with CEAS over a range of 200 nm in the NIR. The measured mixture gas includes CO, CO_2, CH_4, H_2O, and NH_3.[228]

Human breath gas analysis dates back to more than three decades ago. However, real-time, on-line breath gas analysis has been made possible only recently by CRDS or its variants, CALOS, CEAS, and ICOS. The promising application of CRDS in breath analysis for disease diagnostics and metabolic status monitoring can be seen in recent reviews and related publications.[56,219–221,227,229] A current challenge in breath analysis using CRDS and its variants is to eliminate the spectral interference from many other species present in human breath. To address this issue requires more studies on the spectral fingerprints of human breath compounds. Breath gas analysis by CRDS is in its infancy, but we believe that this will be one of the fastest growing areas of CRDS application. Ringdown breath analyzers are expected to become a commercial reality and replace the time-consuming, expensive, and nonportable GC-MS for point-of-care (POC) breath analysis in some situations in the near future.

7 FIBER LOOP RINGDOWN TECHNIQUES

7.1 Introduction

One of the essential characteristics of CRDS is enhanced detection afforded by the long path/multiple interaction approach. This feature has been recently implemented by

Figure 10 Typical measurement of single-breath concentrations of ethane, CO2, and O2. Each single expiration is analyzed separately. Only the first 500 s are displayed. The complete measurement took 42 min. (From ref. 216. Reproduced by permission of Springer. © 2006.)

using a ''conceptual cavity'' – a fiber loop formed by a section of single-mode fiber, thus being generally referred to as *fiber loop ringdown*.[91] This method is modeled after the ringdown concept. However, a conceptually new approach is used, eliminating dependence on an ultrahigh reflectivity cavity. This new fiber ringdown technique utilizes an optical resonator – an optical fiber loop – as the ringdown ''cavity''. Light is coupled into the fiber loop; and when the light source is rapidly shut off, the resultant light rings down inside the fiber loop for many round trips. In each round trip, a small fraction of light leaks to a photodetector through a fiber coupler; and the remaining light rings in the fiber experience internal fiber transmission losses. The signal intensity observed by the detector follows an exponential decay. The lower the losses of the light in the fiber, the longer the decay time constant (ringdown time). When an external action, such as an absorption or evanescent wavefield interaction is applied to a small section of the fiber, the observed ringdown time decreases. This type of fiber ringdown technique functionally resembles the standard high-reflectivity CRDS for absorbance measurements, but without the requirements of high-reflectivity parts.

Figure 11 Schematic of a typical fiber loop ringdown experimental system. (Reproduced from ref. 91 by permission of IOP Publishing Ltd.)

7.2 Fiber Loop Ringdown Chemical Sensors

Culshaw et al. first introduced an optical fiber loop with a length of several tens of meters with a 5-cm open path microoptical gas cell for gas-phase absorption measurement.[91] Figure 11 shows a schematic of the fiber loop ringdown system. Owing to the large insertion loss from the gas cell, an additional Erbium-doped fiber loop was included in the fiber loop to operate just below the threshold for net amplification of the light in the loop. Owing to the excessive optical loss of the laser power in the sensor head (the cell) and large optical insertion losses in the fiber connection/coupling points in the fiber loop, the device showed a short ringdown time, ~100 ns and poor detection sensitivity. On the basis of the same instrument scheme, the same group recently demonstrated an improved version of the device, which yielded ringdown times of up to hundreds of microseconds.[94] Loock's group reported on a simplified fiber loop ringdown technique by introducing a micro air gap into a section of fiber in the fiber loop for detection of a small volume of dye solutions.[6,230] They demonstrated the measurement of 7×10^{-15} mol dye solution using both a CW laser and a pulsed laser. In this study, the laser pulse was coupled into the fiber loop through a direct illumination of a bend in the fiber loop and the detection of the laser pulse leaking out of the fiber was achieved through another bend in the fiber loop. The same group further advanced the fiber loop ringdown technique by introducing phase-shift measurement, which greatly improved the data-acquisition rate to close to real time (10–100 ms).[60] This technique has been demonstrated to be suitable for low-cost, real-time, and on-line detection of capillary electrophoresis with a detection limit at micromolar concentration levels. Using flow injections, the device can detect a series of solution samples at different concentrations. The demonstrated detection limit is 5.3×10^{-12} mol sample in a 530 p-liter volume.[231] Very recently, a minimum fractional absorption of 6 cm^{-1} has been demonstrated by using the fiber loop ringdown technique with a fast gain switch diode laser.[232] In an early publication, Tarsa et al. reported their study on an optical fiber resonator for CRDS, in which the sensor head was made of a section of tapered fiber in the loop and evanescent field absorption was detected.[5,59] A small volume of liquid sample was detected by this type of fiber loop ringdown technique. They also demonstrated the detection of a single-cell adsorption event.[61] Vogler et al. developed a similar fiber loop ringdown device and demonstrated measurement of the diffusion coefficient of hydrogen on silicon through monitoring the OH absorption in the NIR region.[233]

7.3 Fiber Loop Ringdown Physical Sensors

In addition to chemical sensor development using the fiber loop ringdown technique, physical sensors using the fiber loop ringdown concept have been recently demonstrated. Wang and Scherrer extended the fiber loop ringdown

technique for development of low-cost, fast-response, and large-measuring-range pressure sensors.[57,58,234] A section of bare single-mode fiber with a length of 1 cm was used as the sensor head. The sensing principle is primarily based on the fact that micromechanical deformation of the fiber drastically increases optical loss in the fiber loop.[235] The sensor showed repeatable response to pressure, as shown in Figure 12. By using a different baffle layer outside of the bare fiber, different sensing ranges of pressure and/or force can be achieved by the fiber loop ringdown pressure/force sensor. This technique can be further developed for detection and monitoring of mechanical fatigue of materials in an inaccessible and/or harsh environments.

Using a similar fiber loop ringdown approach, Wang and Mbi introduced an optical fiber Bragg grating loop for temperature sensor development.[62,65,236] The Bragg wavelength is temperature dependent. Change of the temperature in the sensor head fiber Bragg grating (FBG) shifts the relative position of the laser wavelength in the FBG wavelength-dependent bandwidth curve, and thus the temperature change results in different transmission rates of the laser beam through the FBG. Different optical losses due to the shift of the FBG curve resulting from the temperature change in the FBG are detected by measuring the ringdown time. One advantage of the fiber FBG loop ringdown temperature sensors is high temperature accuracy. In that work,[65] an accuracy of 0.06 °C was demonstrated in the temperature range of 45–78 °C. Another advantage of the FBG loop ringdown temperature sensor is the low cost compared with the current FBG-optical spectral analyzer (FBG-OSA) temperature sensor. In the FBG loop ringdown temperature sensor, an inexpensive photodiode replaces the expensive optical spectral analyzer (OSA) as the detector. A detailed discussion on the advantages and disadvantages of the FBG loop ringdown temperature sensors compared with the FBG-OSA temperature sensors can be found elsewhere.[65] A schematic of fiber grating loop ringdown sensor is shown in Figure 13.

Figure 12 Fiber loop ringdown pressure sensor's response. (From ref. 57. Reproduced by permission of Optical Society of America.)

By using a long period grating (LPG) as the sensor head, the fiber grating loop ringdown temperature sensor demonstrated a large temperature measuring range, from −169 to 950 °C.[62,65] More recently, a double loop dual sensor head configuration has been developed for multiple location sensing.[237] Using high-temperature composite fiber materials to fabricate a sensor head, such as an FBG or an LPG, high-temperature, fast-response,

Figure 13 Schematic of a typical fiber grating loop ringdown temperature sensor. Section I: the fiber grating loop with an FBG as the sensing element; Section II: the sensor's control portion. (Reproduced from ref. 65 by permission of IOP Publishing Ltd.)

low-cost, fiber grating loop ringdown temperature sensors can be developed for a variety of applications in harsh environments.

8 RINGDOWN INSTRUMENTS

It has been two decades since the first publication of the CRDS technique. Although CRDS has become a mature technique, manufacturing and sale of commercial ringdown instruments for a nonresearch market is a relatively recent event. Owing to the intrinsic nature of the ringdown approach, (e.g. extreme sensitivity to optical and mechanical stability) transitioning the CRDS technique from a research laboratory to a commercial reality is a significant science and engineering achievement. This stride was first successfully made by scientists and engineers at Tiger Optics in 2002[238] with the introduction of a moisture analyzer, the MTO-1000-H_2O. A product line (e.g., H_2O, CH_4, and O_2 ringdown analyzers and tracers) has been subsequently created. Instruments for measuring low concentrations of water and methane in high-purity semiconductor manufacturing gases or in specialty gases are being distributed all over the world. In addition to engineering challenges, a common challenge in ringdown instrumentation is to reduce the instrument cost. Cost is mainly determined by the price of laser sources and high-reflectivity mirrors. Laser cost may not be an issue for instrumentation using inexpensive telecommunications diode lasers; however, for an instrument needing a UV laser source, the availability of compact and low-cost UV laser sources remains a challenge. The effect of mirror cost is diminished when mass production of a ringdown product is implemented. Coating 40 identical high-reflectivity mirrors at a specific wavelength does not cost much more than coating one pair.

9 PERSPECTIVE AND FUTURE DEVELOPMENTS

During the last two decades, CRDS has experienced a full technological cycle, from the introduction of the concept, laboratory fundamental research, to full commercialization of the ringdown instrument. CRDS has had a relatively short cycle through the invention–development–commercialization process. From the analytical spectroscopy point of view, CRDS has brought about a revolutionary change in terms of ultrahigh sensitivity, simplicity, and absolute measurement of trace chemical species in close to real time. The development of this powerful analytical technique coincides with the rapid expansion of new semiconductor materials and telecommunications technologies, which promote rapid advancement of new laser sources and optical fiber components, such as compact, inexpensive, fiber pigtailed laser diodes. The new generation of laser sources, optical coating/polishing technologies, and advanced fiber components allows for continued aggressive development of ringdown instrumentation and applications. CRDS has been demonstrated for trace analysis, environmental monitoring, material processes, medical applications, remote sensing, etc. CRDS has been extensively used to study and detect gas-phase species, and its applications in liquid detection are being aggressively pursued. Theoretical considerations for a total internal reflection ring cavity for thin films and liquids were investigated by Pipino et al. in the early days of CRDS development.[2,239] Engeln et al. have also demonstrated the spectroscopy of thin films by inserting a coated optical flat into a standard ringdown cavity.[100] Loock's group demonstrated promising real-time analytical applications in microfluids using the fiber loop ringdown technique.[63] The detection of a single-cell absorption event represents a start of the ringdown applications in a new field.[61] Snyder and Zare first demonstrated the novel combination of CRDS with high-performance liquid chromatography (HPLC) in 2003.[25] They designed a flow cell with wedged angles that minimized optical losses through all cell surfaces at Brewster's angle; this flow cell was coupled to the output of an HPLC separation for the detection of separated analytes by their absorption properties using CRDS with a pulsed laser. The technique has been extended to use a CW laser and has demonstrated the potential of liquid-phase CW-CRDS to be used as an absorption detector for HPLC measurements.[25] Very recently, Sneppen et al. have demonstrated liquid chromatography (LC)–CRDS using an OPO system to achieve measurements in UV region.[240] Being a powerful measurement technique, the technology associated with the ringdown concept is sure to continue to find new areas of application, such as security screening, food safety inspection, plenary exploration, clean energy study, disease diagnostics, and remote sensing.

and Winstead), DE-FG07-02ER63515 (Winstead and Wang).

ABBREVIATIONS AND ACRONYMS

AOM	Acousto-optical Modulator
CALOS	Cavity Leakout Spectroscopy
CARS	Coherent Anti-Stokes Raman Spectroscopy
CEAS	Cavity Enhanced Absorption Spectroscopy
CRDS	Cavity Ringdown Spectroscopy
CW	Continuous Wave
CW-CRDS	Continuous Wave Cavity Ringdown Spectroscopy
DFB	Distributed Feedback
DFG	Difference Frequency Generation
DFWM	Degenerate Four-wave Mixing
ECDL	External Cavity Diode Lasers
ECDL-CRDS	External Cavity Diode Lasers Cavity Ringdown Spectroscopy
ETA	Electrothermal Atomization
ETA-AAS	Electrothermal Atomization Atomic Absorption Spectroscopy
ETA-CRDS	Electrothermal Atomization Cavity Ringdown Spectroscopy
FBG-OSA	Fbg-optical Spectral Analyzer
FFT-CRDS	Fast Fourier Transform Cavity Ringdown Spectroscopy
GC	Gas Chromatography
GC-MS	Gas Chromatograph Mass Spectrometry
HPLC	High-performance Liquid Chromatography
ICOS	Integrated Cavity Output Spectroscopy
ICP	Inductively Coupled Plasma
ICP-CRDS	Inductively Coupled Plasma Cavity Ringdown Spectroscopy
ICP-LIF	Inductively Coupled Plasma Laser-induced Fluorescence
ICP-MS	Inductively Coupled Plasma Mass Spectrometry
IR	Infrared
IRMS	Isotope Ratio Mass Spectroscopy
LC	Liquid Chromatography
LIF	Laser-Induced Fluorescence
LPG	Long Period Grating
LTE	Local Thermoequilibrium Approximation
MIP	Microwave Induced Plasma
MIP-CRDS	Microwave Induced Plasma Cavity Ringdown Spectroscopy
MPT	Microwave Plasma Torch
MPT-CRDS	Microwave Plasma Torch Cavity Ringdown Spectroscopy
OES	Optical Emission Spectrometry
OF-CRDS	Optical Feedback Cavity Ringdown Spectroscopy
OPO	Optical Parametric Oscillator
OSA	Optical Spectral Analyzer
P-CRDS	Plasma Cavity Ringdown Spectroscopy
POC	Point-of-care
PPLN	Periodically Poled Lithium Niobate
QCLs	Quantum Cascade Lasers
REMPI	Resonantly Enhanced Multiphoton Ionization
REMPI-TOF-MS	Resonance-Enhanced Multiphoton Ionization Time-of-flight Mass Spectrometry
T1D	Type 1 Diabetes
VOCs	Volatile Organic Compounds
UV	Ultraviolet

Infrared emission spectroscopy (IRES) is a branch of experimental infrared (IR) spectroscopy that can be considered as an alternative to the more commonly used IR absorption or reflection techniques for observing vibrational transitions in molecular systems. While these methods provide spectral data that are similar regarding their information content (structural, analytical), IRES may have definite advantages (or drawbacks) depending on the object to be studied.

This article aims at giving an up-to-date account of the theory, instrumentation and laboratory practice of IRES. Following an introduction to the principles and nature of thermal radiation, the governing laws of IRES are outlined and analyzed in some depth, with the aim of defining the conditions for obtaining analytically meaningful IR emission spectra. Spectral distortions concomitant with the measurement of condensed-phase samples and other sources of error are pointed out along with the procedures devised for their elimination. Various methods of excitation of thermal radiation and the instrumentation most often used in laboratory measurements of IR emission spectra are described, with emphasis on modern Fourier transform (FT) techniques and with an outlook to special applications like remote sensing and process monitoring. Attention is given to data manipulation and presentation of emission spectra in relation to quantitative evaluation of spectral data. Recent advances in sample handling techniques, for example allowing the measurement of optically thick samples or thin surface layers, are also reviewed, while reference is given to the original sources of literature in the field.

1 INTRODUCTION

IRES is concerned with the analysis of energy distribution, as a function of frequency (wavenumber) or wavelength, of the electromagnetic radiation emitted by objects (samples) in the IR spectral region. The IR region of the electromagnetic spectrum is usually considered to be from 4000 to 400 cm^{-1} (2.5 to 250 μm), or including also the near-infrared (NIR) and far-infrared (FIR) regions – from 14 000 to 10 cm^{-1} (0.7–1000 μm). Emission encountered in this spectral region is associated with vibrational, vibrational-rotational or pure rotational motions of molecules. Since these quantized motions may be more or less excited at temperatures higher than absolute zero (0 K = −273.15 °C = −459.67 °F), their relaxation leads to emission of *thermal* (mostly IR) radiation. Thermal excitation is the most common excitation mechanism of IR emission of gases, liquids and solids, and we will focus here on spectroscopic aspects of this phenomenon. Other excitation mechanisms such as chemiluminescence or photoluminescence will not be dealt with in detail as they are governed by somewhat different laws.

IR emission spectra of various objects can be continuous or discontinuous. The spectral distribution of energy in the continuous (or blackbody-like) emission spectra are characteristic only of the temperature of the emitter, while discontinuous spectra containing narrow emission bands or lines are characteristic of its material properties as

Encyclopedia of Analytical Chemistry

well. The goal of IR emission spectroscopic measurement is the same as that of IR spectroscopy in general: to get an insight, through the observable spectral features of the objects, into the chemical composition, molecular structure, configuration and conformation of the molecules, the nature of chemical bonding and intermolecular interactions within the sample. If the spectral features can be assigned to known chemical species, the measured emission spectral data can be utilized in qualitative or quantitative analysis, in much the same way as in the more commonly used infrared absorption spectroscopy (IRAS). Depending on the samples and conditions of measurement (temperature, physical state, energy conditions) one or the other IR spectroscopic observation technique may be preferred. A special topic of IRES of great theoretical interest is the investigation of highly excited vibrational and vibrational-rotational states, not conveniently accessible to absorption studies.

In laboratory practice, the instruments used for the measurement of IR emission spectra are essentially the same as those used in IRAS, with a difference in sample arrangement: in IRES the emitting sample replaces the standard light source or it is put in an optically equivalent position (often in an auxiliary sample compartment outside the instrument cover). In principle, any type of IR spectrometer is capable of measuring IR emission spectra, but since the radiation to be detected may be rather weak (when the sample temperature is relatively low), high-performance FT (interferometric) spectrometers are preferred to dispersive instruments owing to their higher optical throughput and other known advantages leading to higher sensitivity.

Thus, a typical Fourier transform infrared (FTIR) instrument used for the measurement of IR emission spectra consists of an emission port (receiving the radiation from the auxiliary emission accessory), a modulator (interferometer) and a broad-range IR detector. The IR radiation emitted by the sample enters the interferometer in the form of a collimated beam where it gets modulated, then is focused on the detector. The analog signal of the interferogram is measured at equidistant data points and is converted to digital data, by means of an analog-to-digital converter (ADC). As a rule, the interferogram is measured repeatedly many times and the data are accumulated (averaged) to increase the signal-to-noise ratio (S/N). The so-called single-beam emission spectrum (the energy spectrum) is obtained from the interferogram via Fourier transformation by means of a PC or dedicated microcomputer. Double-beam emittance spectra (corresponding to transmittance spectra in absorption spectroscopy) are obtained by ratioing the single-beam emission spectrum of the sample to that of a laboratory blackbody, used as reference, measured under the same conditions (same temperature) as the sample.

The applicability and potentials of IRES as a method of measurement to solve analytical problems must be considered in comparison with those of IR absorption and reflection techniques. One of the main advantages of IRES stems from its single-ended measurement geometry, which means that the sample need not be put inside the instrument: it should be accessible only from one side or is seen from a distance. This makes IRES one of the basic methods for remote sensing, e.g. of natural sources of thermal radiation such as hot gases, and explains its widespread application in environmental, atmospheric, extraterrestrial or astrophysical research. The same applies to in situ measurements for process control, e.g. in the chemical industry. In laboratory conditions IRES is preferred when very hot or chemically aggressive samples have to be examined which cannot be or would be risky to place into the sample compartment of a spectrometer. The IR emission technique is equally applicable to smooth and rough surfaces, and can be used with transparent and nontransparent substrates such as metals. Thin overlayers on metal surfaces (e.g. lubricants on moving machine parts) are ideal samples for IRES without any sample preparation, and chemisorbed molecules on metal single crystal surfaces can be detected even at monomolecular coverage when using special detection techniques.

The principal drawback to IRES is that for IR emission to occur, a molecule must go from an excited vibrational state back to the ground state; and in order to have a detectable flux of such radiation, there must be a significant proportion of molecules in the excited state. To achieve such a population of vibrational modes whose transitions are observed in the mid-IR region, the sample must be heated, which may not only be inconvenient but also injurious to many substances, especially those of organic origin. A further difficulty is introduced by background emission: the emission of the hot surroundings of the sample, which may overwhelm the signal from the sample of interest. Thus, for practical applications of IRES, a restricting condition is that during measurement the sample must be kept at a constant temperature differing from that of the spectrometer (detector).

Furthermore, with condensed-phase samples, IRES is limited to the examination of thin layers not exceeding a few micrometers in thickness – just as in transmission. Measurement of the surfaces of much thicker samples or thin overlayers on top of opaque substrates is not a simple task; it requires special sample handling methods such as transient heating or cooling to obtain meaningful emission spectra. Since IR emission is often accompanied by undesirable absorption and reflection phenomena and heat transfer that may disturb the observation or distort the emission spectrum, a good understanding of the

underlying laws and principles is needed to set up the right measurement conditions.

Several earlier reviews on IRES are available in the literature reflecting the state of the art and the field of interest of the time of their publication.[1–6] Our presentation will necessarily overlap with these, while illuminating some new topics of present-day interest.

2 THEORETICAL BACKGROUND

2.1 Basic Terms and Principles

2.1.1 Infrared Radiation

Just like visible light, IR radiation is part of the spectrum of electromagnetic waves. At the same time it may also be considered as consisting of massless energy parcels called photons. In fact, both descriptions are needed to account for all radiative and optical phenomena that have been observed.

An electromagnetic wave may be identified by its wavelength (λ), frequency (ν), or wavenumber ($\tilde{\nu}$). These three quantities are related to each other through Equation (1):

$$\tilde{\nu} = \frac{\nu}{c} = \frac{1}{\lambda} \tag{1}$$

where c is known as the speed of light (actually, it refers to the velocity of all kinds of electromagnetic radiation); in vacuum $c = c_0 = 2.99792458 \times 10^8\,\mathrm{m\,s^{-1}}$. Note that the speed of light depends on the medium in which the wave travels, and may be related to the speed of light in vacuum, c_0, by Equation (2):

$$c = \frac{c_0}{n} \tag{2}$$

where n is the refractive index of the medium. By definition, the refractive index of vacuum is unity ($n \equiv 1$), while for any other media it is greater: for most gases it is very close to 1 (for air $n = 1.0003$ in the visible part of the spectrum), but most dielectric media have n values as great as 1.4 to 4.

The wavelength, λ (expressed in $\mu\mathrm{m} = 10^{-6}\,\mathrm{m}$), is a quantity that can be measured experimentally (e.g. with an interferometer). The wavelength scale was introduced in spectroscopy in 1868 and has been used since, mainly in the ultraviolet (UV) and visible regions. The frequency, ν, is defined as the number of waves that pass a given point in one second (measured in cycles/s $= \mathrm{s^{-1}} = \mathrm{Hz}$). However, in the IR region it is more practical to divide the actual frequency value with the speed of light and replace it with the much smaller value obtained, the wavenumber, $\tilde{\nu}$, which gives the number of waves in one centimeter of vacuum, leading to its units as $\mathrm{cm^{-1}}$. It is this spectral variable and measurement unit that are almost exclusively used in IR spectroscopy (although the wavenumber values are often referred to as ''frequencies'' in the spectroscopists' slang).

An electromagnetic wave or photon carries with itself an amount of energy, E, proportional to its frequency, (Equation 3):

$$E = h\nu = hc\,\tilde{\nu} \tag{3}$$

where $h = 6.62608 \times 10^{-34}\,\mathrm{J\,s}$ is known as the Planck constant. The unit of energy most often used in connection with photons or electromagnetic waves is the electron volt, eV ($1\,\mathrm{eV} = 1.6022 \times 10^{-19}\,\mathrm{J}$). The energy of the photon is conserved as light passes from one medium to another, which means that the frequency of light does not change at the interface. Note, however, that in accordance with Equations (1) and (2), wavelengths and wavenumbers do change when light enters another medium with a different refractive index. (However, in everyday applications of spectroscopy this dependence is generally neglected, i.e. wavenumber values pertaining to vacuum are used.)

The arrangement and limiting values of the different regions of the electromagnetic wave spectrum are shown in Figure 1 in terms of the above mentioned scales. The terms IR emission and thermal radiation are often used as synonyms; in fact, thermal radiation, defined as electromagnetic waves that are emitted by a medium owing solely to its temperature, may extend from IR through the visible spectrum into the near UV region in case of very hot emitters (e.g. incandescent light sources, or the sun).

2.1.2 Principles of Thermal Radiation

All media continuously emit electromagnetic radiation, randomly in all directions, depending on their

Figure 1 Thermal radiation in the spectrum of electromagnetic radiation.

temperature and on the properties of their material. Radiation emitted by a homogeneous medium is also homogeneous, unpolarized and isotropic. Before discussing the quantitative laws of thermal radiation that are fundamental to IR emission spectroscopy of gases, liquids and solids, a general acquaintance with the nature of thermal radiation and thermal equilibrium may be appropriate.

Any emission of IR or thermal radiation is concomitant with some loss of energy of the emitter. Since objects at a temperature of absolute zero (0 K) are at their lowest possible energy level, they are obviously unable to emit any energy in that state. But at higher temperatures a certain proportion of molecules are rotationally and vibrationally excited (electronic excitation takes place at much higher than room temperature), and these molecules spontaneously emit energy in the form of thermal radiation while relaxing to lower-lying energy levels. At the same time the surrounding molecules or objects may absorb some of the emitted photons and get excited. Thus there is a continuous radiative exchange of energy leading to redistribution and equalization of temperature within a thermally isolated system.

Let us consider an evacuated enclosure with totally reflecting inner walls, thermally isolated from the outside, containing two objects of similar mass and different temperature. In accordance with the general experience, the two objects will, in time, have the same temperature. Since heat conduction and convection is excluded in vacuum, the only interaction between the two objects leading to this result is thermal radiation. As was discovered at the beginning of the 19th century (C. Prévost, 1809), any object emits energy depending on its own temperature, irrespective of the temperature of the surroundings. Thus in our example the hotter object initially emits more energy than it absorbs and gets cooler, while the cooler object absorbs more energy than it emits and gets warmer, until thermal equilibrium sets in. At thermal equilibrium the objects emit just as much radiant energy per second as they absorb, thus there is also radiation equilibrium, i.e. a uniform radiation field inside the enclosure.

The outcome of our fictional experiment will be the same if one of the objects in the isolated enclosure is absolutely black throughout the spectrum (usually referred to as blackbody) and the other is not. But since the blackbody absorbs all radiation falling on it, at thermal equilibrium it must also emit the same amount of energy. The other object may absorb less (and reflect or transmit the rest) but then it will also emit less than the black object. By this reasoning we discover a one-to-one correspondence between absorptance (α) and emittance (ε) of an object, an important law discussed in more detail in section 2.3.

2.1.3 Radiant Energy

The radiation field is characterized by its radiant energy density, H, defined in Equation (4) as

$$H = \frac{Q}{V} \tag{4}$$

where Q is the total radiant energy and V is the volume. The radiation field is composed of radiation of various frequencies or wavelengths, which can be represented by Equation (5):

$$H = \int_0^\infty H_\nu \times \mathrm{d}\nu = \int_0^\infty H_{\tilde{\nu}} \times \mathrm{d}\tilde{\nu} = \int_0^\infty H_\lambda \times \mathrm{d}\lambda \tag{5}$$

where H_ν, $H_{\tilde{\nu}}$, and H_λ are the spectral radiant energy densities expressed in terms of frequency, wavenumber and wavelength, respectively. (''Spectral'' in these terms indicates that the radiant energy density is a function of the actual spectral variable, and is considered within the spectral intervals (ν, $\nu + \mathrm{d}\nu$), ($\tilde{\nu}$, $\tilde{\nu} + \mathrm{d}\tilde{\nu}$) or ($\lambda$, $\lambda + \mathrm{d}\lambda$) respectively.)

2.1.4 Energy Levels, Transitions and Emission Probability

The total energy of a molecular system is composed of the energy of electronic, vibrational and rotational motions and, according to quantum theory, it can assume discrete values depending on quantum numbers that specify the level of excitation of each type of motion. Any absorption or emission of IR radiation is associated with transitions between vibrational or vibrational-rotational energy levels (Figure 2), whereas the amount of energy absorbed or released, ΔE, is proportional to the frequency, ν, or wavenumber, $\tilde{\nu}$, of the radiation (Equation 6):

$$\Delta E = E_j - E_i = h\nu = hc\,\tilde{\nu} \tag{6}$$

Figure 2 Energy levels in the potential energy curve of a diatomic molecule; arrows drawn with full line signify absorption, arrows with dotted lines signify emission.

where E_j is the energy of the upper level, E_i is that of the lower level. Transition from a higher to a lower energy state (designated as $E_j \rightarrow E_i$) is accompanied by emission of energy, while transition from lower to higher energy states ($E_j \leftarrow E_i$) is concomitant with absorption of energy. The energy levels and transitions between them are often characterized, instead of the energies, by the so-called term values obtained when both sides of Equation (6) are divided by hc, leading to quantities given in units of cm^{-1}. The frequent use of Equation (6) justifies that in IR spectroscopy priority is given to the wavenumber scale and the cm^{-1} units.

A molecule consisting of N atoms has, in general, $3N - 6$ vibrational degrees of freedom. Depending on the atomic masses, the geometrical arrangement of atoms within the molecule and the forces acting between them, an equal number of so-called normal vibrations will be formed, each of them having a well-defined fundamental vibrational frequency, ν_k, associated with a specific form or mode of vibration, and a series of quantized energy levels. According to the theory of molecular vibrations,[7] at a temperature of absolute zero no vibrational modes are excited (all normal modes assume their zero-point motions), and the vibrational energy of the system is at its minimum. However, at higher temperatures, when the molecules are in thermal equilibrium with their surroundings, a certain portion of them is always at thermally excited vibrational and rotational levels (excitation of electronic energy takes place at much higher temperatures than normal room temperature). The excited molecules spontaneously emit energy in the form of electromagnetic radiation. The intensity of an emission line belonging to transition $j \rightarrow i$, defined as the amount of energy emitted by the sample per second, is determined by Equation (7):

$$I_{ij} = N_j hc\,\tilde{\nu} A_{ij} \tag{7}$$

where N_j is the number of molecules in the excited state j, and A_{ij} is the transition probability (also known as the Einstein coefficient of spontaneous emission). The population of an excited state, N_j, relative to that of the initial (lower) state, N_i, as a function of temperature is governed by Boltzmann statistics (Equation 8):

$$\frac{N_j}{N_i} = \exp\ \frac{-(E_j - E_i)}{kT}\ = \exp\ \frac{-hc\,\tilde{\nu}}{kT} \tag{8}$$

where $k = 1.380658 \times 10^{-23}\,J\,K^{-1}$ is the Boltzmann constant and T is the absolute temperature. Thus the fraction of excited molecules decays exponentially with the excitation energy but increases with temperature. For instance, at 300 K for a vibration at $200\,cm^{-1}$ the value of N_j/N_i is expected to be 0.38, while for a $1000\,cm^{-1}$ vibration it is only 0.0008; at 500 K these values become about 0.56 and 0.06, respectively. The transition probability of spontaneous emission is defined as the fraction of molecules undergoing transition from the excited state j to the lower state i per second, and can be calculated as in Equation (9):

$$A_{ij} = \frac{64\pi^4 \tilde{\nu}_{ij}^3}{3h} |\vec{M}_{ij}|^2 \tag{9}$$

where the transition moment (roughly: the change of the electric dipole moment vector, $\vec{\mathbf{M}}$, during the vibrational or rotational transition), $\vec{M}_{ij} = \int \psi_j^* \hat{\mathbf{M}} \psi_i d\tau$, with ψ_i and ψ_j being the eigenfunctions of the initial and final states, respectively, and $\hat{\mathbf{M}}$ the electric dipole moment operator.

The above relations provide the general theoretical basis for prediction of band intensities in the emission spectrum. It has been recognized, however, that the limiting values of these intensities are those obtained for an absolute blackbody, and it is more practical to relate the emission spectrum of a sample to that of the blackbody.

2.2 The Laws of Blackbody Radiation

2.2.1 Stefan–Boltzmann Law

Much of the early classical research on thermal radiation was devoted to the search for the correct form of the spectral radiant energy density of blackbody, $H_{\tilde{\nu}}$, as a function of frequency (or wavelength) and temperature. But before that problem could be solved, the temperature dependence of the total radiant energy density of the radiation emitted by a blackbody, H, was established by Stefan experimentally (1878) and confirmed by Boltzmann theoretically (1884). The relation they obtained is known as the Stefan–Boltzmann law (Equation 10):

$$H = \sigma \times T^4 \tag{10}$$

with $\sigma = 2\pi^5 k^4/15c^2h^3 = 5.6705 \times 10^{-8}\,W\,m^{-3}\,K^{-4}$ being the Stefan–Boltzmann constant (where $k = 1.380658 \times 10^{-23}\,J\,K^{-1}$ is the Boltzmann constant).

2.2.2 Wien's Displacement Law

Two partially successful approximations to the spectral distribution of the blackbody radiation were published around the end of the 19th century, the Rayleigh–Jeans law, acceptable only for low frequencies, and Wien's radiation law, quite accurate for the high-frequency region; now they are only of historical value. Another empirical law discovered prior to the right form of the blackbody radiation function is Wien's displacement law

(Equation 11) relating the frequency of the maximum of blackbody radiation to the absolute temperature:

$$\tilde{\nu}_{\max} = \text{const} \times T \tag{11}$$

2.2.3 The Planck Function

The correct analytical form of the spectral distribution of blackbody radiation was found by M. Planck in 1900 as an interpolation formula between the above-mentioned two approximations; soon afterwards he established his finding theoretically as well by extending Boltzmann statistics with the quantization condition for the emitted energy. The distribution function he obtained this way had integrated in itself all radiation laws established earlier and is known as Planck's law of blackbody radiation or the Planck function. It is also in agreement with all observed data. The actual form of the Planck function depends on whether it is expressed in terms of frequency, wavenumber or wavelength. In the frequency representation (Equation 12), the density of radiant energy emitted from a unit area of the blackbody source per solid angle in spectral element $d\nu$ is:

$$H_\nu(T)\,d\nu = \frac{2hc^{-2}\nu^3}{e^{h\nu/kT} - 1}\,d\nu \tag{12}$$

(Variations of the Planck function containing a factor of 8π instead of 2 in the above equation refer to radiance considered in the whole solid angle.)

The wavenumber and wavelength representations can be obtained from Equation (12) through Equation (13):

$$\nu = c\tilde{\nu} = \frac{c}{\lambda} \quad \text{and} \quad d\nu = c\,d\tilde{\nu} = -\frac{c}{\lambda^2}\,d\lambda \tag{13}$$

and using the equivalence of the three representations expressed in Equation (5), to give Equations (14) and (15):

$$H_{\tilde{\nu}}(T)\,d\tilde{\nu} = \frac{2hc^2\tilde{\nu}^3}{e^{hc\tilde{\nu}/kT} - 1}\,d\tilde{\nu} \tag{14}$$

and

$$H_\lambda(T)\,d\lambda = \frac{2hc^2}{\lambda^5(e^{hc/\lambda kT} - 1)}\,d\lambda \tag{15}$$

It is customary to introduce the so-called first and second radiation constants, C_1 and C_2, having the values given in Equations (16) and (17):

$$C_1 = 2hc^2 = 1.1911 \times 10^{-12}\,\text{J cm}^2\,\text{s}^{-1} \tag{16}$$

and

$$C_2 = \frac{hc}{k} = 1.4388\,\text{cm K} \tag{17}$$

and write the Planck function in the wavenumber representation simply as Equation (18):

$$H_{\tilde{\nu}}(T) = \frac{C_1\tilde{\nu}^3}{e^{C_2\tilde{\nu}/T} - 1} \tag{18}$$

which is more practical to use when only the relative energy distribution is important (C_1 may be adjusted to fit the actual application).

Note that Equations (12) and (14) are the same within a constant factor, while Equation (15) describes curves of essentially different shapes, with their maxima shifted considerably toward higher wavenumbers. Thus there are two basically different representations of the Planck function, as shown in Figure 3 (in the same linear wavenumber scale, for three different temperatures). Correspondingly, also Wien's displacement law (Equation 11) has two versions, Equations (19) and (20):

$$\tilde{\nu}_{\max}[\text{cm}^{-1}] = 1.93 \times T[\text{K}] \tag{19}$$

for Equation (10), and

$$\lambda_{\max}[\text{cm}] = \frac{0.283}{T[\text{K}]} \tag{20}$$

for Equation (15), and these relations give different maxima for the same temperatures. One has to have a clear idea which of these forms are to be used when applied to IR emission spectroscopy. Seeking the connection with the measurement of blackbody emission spectra, the curves shown in Figure 3 in full line (wavenumber version, Equation 14) can be obtained if the spectrum is scanned with a spectral slit constant in wavenumber (or frequency), while those shown in broken line would be obtained if the spectrum were

Figure 3 Theoretical blackbody radiation curves (Planck functions) for three different temperatures in the wavenumber representation (full lines) and in the wavelength representation (broken lines).

Figure 4 Comparison of blackbody emission spectra measured on a Digilab FTS-20C spectrometer at 60 and 100 °C (with deuterated triglycine sulfate (DTGS) detector at 29 °C) with uncorrected Planck functions (a), and with Planck functions corrected for detector temperature (b). (Reproduced by permission of the Society for Applied Spectroscopy from Keresztury, Mink, *Appl. Spectrosc.*, **46**, 1747–1749 (1992).[9])

scanned with a spectral slit constant in wavelength. Since modern interferometric (FT) IR spectrometers yield spectra with constant resolution in the wavenumber scale in the whole working region, it is imperative that with FTIR instruments the wavenumber version of the Planck function be used (i.e. Equation 14 or 18) whenever a theoretical blackbody reference spectrum is needed.

Another pitfall that should be avoided when theoretical and experimental blackbody emission spectra are compared (e.g. in order to determine the emitter's temperature or to find the instrument response function) is to assume that all radiation collected is also detected by the instrument. From the principles of thermal radiation we know that the detector (which is supposed to be as nearly a blackbody as possible) also emits thermal radiation at temperatures higher than absolute zero. Since IR detectors can respond only to deviations from radiation equilibrium, the detector does not 'see' all radiation falling on it, only the difference of the blackbody-like emissions from the sample and from the detector (no matter which of them is at higher temperature).[8] Thus, if a room-temperature detector is used and the sample temperature is not very high, the measured spectrum is related to the difference of the corresponding Planck functions.[9] This is illustrated in Figure 4.

2.3 Thermal Radiation of Nonblackbodies

When a monochromatic beam of light of unit intensity falls on a slab of condensed-phase material (see Figure 5a), it is divided into three fractions: one may be reflected off the surface, another is absorbed inside the layer and the remainder is transmitted, so that (if scattering and luminescence are neglected) these three fractions add up to unity (Equation 21):

$$\alpha + \rho + \tau = 1 \tag{21}$$

where α, ρ and τ are known as the absorptance (or absorption factor), reflectance (reflection factor) and transmittance (transmission factor) of the sample, respectively. (The same quantities are sometimes erroneously

Figure 5 Schematics of (a) irradiation of a semitransparent slab, and (b) observation of emission by a supported slab.

called absorptivity, reflectivity and transmissivity in the literature. The terms with the ending -ance refer to properties of a body (with a given composition, shape, etc.), while the terms with the ending -ivity should refer to properties of a substance measured under standard conditions.)

By definition, a blackbody absorbs all radiation falling on it, thus the absorptance of a blackbody is unity at all frequencies, (Equations 22–24):

$$\alpha = 1 \quad \text{and} \quad \rho = \tau = 0 \tag{22}$$

At another extreme, for a shiny, reflecting metal surface

$$\rho \approx 1 \quad \text{and} \quad \alpha \approx \tau \approx 0 \tag{23}$$

while for an ideal spectroscopic window material

$$\tau \approx 1 \quad \text{and} \quad \alpha \approx \rho \approx 0 \tag{24}$$

However, for most of the common materials, α, ρ and τ are not only between 0 and 1 but strongly wavenumber-dependent as well. They may have narrow absorption lines or broader absorption bands at specific frequencies, and the reflectance may also change in the vicinity of the peaks of strong absorption bands. Those objects for which α, ρ and τ have intermediate values between 0 and 1 throughout the whole spectrum are called graybodies. The ideal laboratory blackbody does not exist; blackbody samples used in emission measurements as reference are, in fact, graybodies that have absorptance or emittance above 0.90 (some may come close to 0.99) in a very broad spectral interval.

2.3.1 Kirchhoff's Law

One of the basic principles of IRES is the principle of equivalence of absorptance and emittance (discovered by G.W. Kirchhoff in 1860). In its original form Kirchhoff's law (Equation 25) states that the ratio of the spectral luminance (or radiant flux) of any sample, L_s, at a given temperature, T_i, to its absorptance, α_s, equals the luminance of the blackbody, L_{bb}, at the same temperature.

$$\frac{L_s(\tilde{\nu}, T_i)}{\alpha_s(\tilde{\nu})} = L_{bb}(\tilde{\nu}, T_i) \tag{25}$$

which implies that $\alpha_{bb} = 1$. At the same time the emittance of a sample, $\varepsilon_s(\tilde{\nu})$, is defined (Equation 26) as the ratio of the radiant flux emitted by the sample (L_s) to the flux emitted by a blackbody (L_{bb}) at the same temperature:

$$\varepsilon_s(\tilde{\nu}) = \frac{L_s(\tilde{\nu}, T_i)}{L_{bb}(\tilde{\nu}, T_i)} \tag{26}$$

L_s may be regarded as the observed luminance of the sample or, as it is often referred to, its single-beam emission spectrum (see also section 2.4). Comparison of Equations (25) and (26) yields Equation (27):

$$\varepsilon_s(\tilde{\nu}) \equiv \alpha_s(\tilde{\nu}) \tag{27}$$

which is the essence of Kirchhoff's law.

According to this, if a sample absorbs light of a certain frequency, it will also emit at the same frequency. Moreover, this relation means that not only the frequencies but also the so-called selection rules that determine the band intensities will be the same for absorption and emission processes involving the same energy levels of the molecule.

Thus, substituting emittance for absorptance in Equation (21) one gets the basic relation of optical emission spectroscopy (Equation 28):

$$\varepsilon(\tilde{\nu}) + \rho(\tilde{\nu}) + \tau(\tilde{\nu}) = 1 \tag{28}$$

This relation has to be taken into account when choosing the materials for building an emission cell or when interpreting IR emission spectra of condensed materials.

2.4 Practical Aspects of Theory

It follows from Equations (22) and (27) that a blackbody (with $\alpha = 1$) is an ideal emitter (Equation 29):

$$\varepsilon_{bb} = 1 \quad \text{and} \quad \rho_{bb} = \tau_{bb} = 0 \tag{29}$$

Since these conditions are valid for all parts of the spectrum, no material can emit more energy at any given frequency and at any given temperature than a blackbody.

For other types of materials with properties described by Equations (23) and (24) analogous relations can be obtained by substituting emittance for absorptance. Thus, a shiny metal surface is a very poor emitter ($\varepsilon = \alpha \approx 0$), so it makes an excellent back-plate for the sample. In contrast, IR-transmitting cell windows are rarely used as back-plates in IRES since they transmit background radiation.

Nonblackbodies or graybodies in general have emittance

$$\varepsilon(\tilde{\nu}) = 1 - \tau(\tilde{\nu}) - \rho(\tilde{\nu}) \tag{30}$$

in the range of 0 to 1, which changes with wavenumber (Equation 30).

An opaque body's transmittance is zero ($\tau_{op} = 0$) but its reflectance may be significant in some spectral regions ($\rho(\tilde{\nu}) \neq 0$), therefore (Equation 31):

$$\varepsilon_{op}(\tilde{\nu}) = \alpha_{op}(\tilde{\nu}) = 1 - \rho(\tilde{\nu}) \tag{31}$$

Figure 6 Comparison of emission and absorption spectra of a poly(methyl methacrylate) (PMMA) film: (a) Single-beam emission spectrum of PMMA film on an Al foil at 120 °C; (b) blackbody reference emission spectrum at 120 °C; (c) double-beam emittance spectrum of PMMA obtained as a ratio of A to B; (d) transmittance spectrum of the same PMMA film measured in reflection–absorption mode (* indicates chloroform inclusion bands).

In molecular spectroscopy one is usually interested in internal properties of the sample, when surface effects may be neglected ($\rho \approx 0$); in this case (Equation 32):

$$\varepsilon(\tilde{\nu}) \approx 1 - \tau(\tilde{\nu}) \tag{32}$$

which shows the complementary nature of transmittance and emittance spectra. The spectra in Figure 6 illustrate this relation: the emittance spectrum of a PMMA film on an Al foil (Figure 6c) was obtained by ratioing the single-beam emission spectrum of the sample (Figure 6a) to that of a blackbody reference (Figure 6b); the transmittance spectrum shown for comparison (Figure 6d) was measured in reflection–transmission mode.

2.4.1 Single- and Double-beam Emission Spectra and Background Effects

Rearranging Equation (26) one obtains $L_s(\tilde{\nu})$, the single-beam emission spectrum of the sample (Equation 33):

$$L_s(\tilde{\nu}, T_i) = \varepsilon_s(\tilde{\nu}) \times L_{bb}(\tilde{\nu}, T_i) \tag{33}$$

This relation shows that the so-called single-beam emission spectrum of any sample at a certain temperature can be viewed as its emittance, $\varepsilon_s(\tilde{\nu})$, modulated by the blackbody radiation spectrum corresponding to the same temperature.

In the ideal case, if the detector received radiation only from the sample and responded to it perfectly, $L_{bb}(\tilde{\nu}, T_i)$ could be replaced by the corresponding Planck function, $H(\tilde{\nu}, T_i)$, yielding Equation (34):

$$L_s(\tilde{\nu}, T_i) = \varepsilon_s(\tilde{\nu}) \times H(\tilde{\nu}, T_i) \tag{34}$$

However, the actually measured spectra are affected by background radiation, $B(\tilde{\nu})$, and by imperfections of the instrument used. To account for these effects one can write Equation (35):[8]

$$L_s(\tilde{\nu}, T_i) = R(\tilde{\nu}) \times [\varepsilon_s(\tilde{\nu}) \times H(\tilde{\nu}, T_i) + B(\tilde{\nu})] \tag{35}$$

where $R(\tilde{\nu})$ is the instrument response function (in the ideal case $R(\tilde{\nu}) = 1$). $B(\tilde{\nu})$ represents background radiation of different origin often written as the sum of two terms, $B(\tilde{\nu}) + I(\tilde{\nu}) \times \rho(\tilde{\nu})$, to distinguish between self-radiation of the instrument, and outside radiation reflected off the sample. Equation (35) assumes a detector kept at or near 0 K, which is rarely the case. With liquid-nitrogen-cooled detectors ($T_d = 77$ K) Equation (35) is a good approximation. However, if a room-temperature detector is used which emits a fair amount of energy, the above equation must be extended to Equation (36), with one more term corresponding to its radiation:[10]

$$L_s(\tilde{\nu}, T_i, T_d) = R(\tilde{\nu}) \times [\varepsilon_s(\tilde{\nu}) \times H(\tilde{\nu}, T_i) - \varepsilon_d(\tilde{\nu}) \times H(\tilde{\nu}, T_d) + B(\tilde{\nu})] \tag{36}$$

where ε_d is the emittance of the detector and T_d is its temperature (note the negative sign of the added term, meaning opposite direction of that radiation flux).

A similar relation can be written (Equation 37) for the measured single-beam emission spectrum of the laboratory blackbody reference:

$$L_{bb}(\tilde{\nu}, T_i, T_d) = R(\tilde{\nu}) \times [H(\tilde{\nu}, T_i) - H(\tilde{\nu}, T_d) + B(\tilde{\nu})] \quad (37)$$

where it has been assumed that $\varepsilon_{bb}(\tilde{\nu}) = \varepsilon_d(\tilde{\nu}) = 1$.

Now the emittance of the sample, $\varepsilon_s(\tilde{\nu})$, cannot be obtained as the ratio of L_s and L_{bb}, as has been defined in Equation (26), unless the last two terms in Equation (36) are eliminated. The standard procedure to do it involves making four measurements:[11] the emission spectra of both the sample and the blackbody reference are measured at two temperatures; then, assuming that the sample emittance is independent of temperature over the operating range, the emittance of the sample can be calculated as the ratio of the increase in sample luminance to that of the blackbody luminance (Equation 38):

$$\varepsilon_s(\tilde{\nu}) = \frac{L_s(\tilde{\nu}, T_2) - L_s(\tilde{\nu}, T_1)}{L_{bb}(\tilde{\nu}, T_2) - L_{bb}(\tilde{\nu}, T_1)} \quad (38)$$

where $T_2 > T_1$. Substituting the full expression for luminances from Equations (36) and (37) into Equation (38) it can be seen that using this procedure, which is referred to as background correction,[8] all terms that do not depend on sample temperature are, in principle, eliminated.

When a low-temperature detector is used, $B(\tilde{\nu})$ includes radiation emitted by the surface of the beamsplitter in the interferometer (oxide species formed on the surface of the semi-transparent Ge layer) mainly responsible for the so-called instrument self-emission. It has been found[11] that subtraction of the interferograms rather than the single-beam spectra in Equation (38) leads to better compensation of the beamsplitter emission, since this avoids some phase-correction problems. Radiation originating in the beamsplitter suffers a different number of reflections in the interferometer than radiation coming from the sample, which creates different phase relations for this part of the signal, not correctly accounted for in the process of phase correction that follows Fourier transformation.[12] Figure 7 shows a typical example of background correction in the case of a cooled MCT detector.[8] One can see that the spectral features can be identified in the uncorrected spectrum (broken line) as well, but the relative intensities are strongly altered. Hence, in quantitative analysis based on emission spectra background correction is obligatory.

2.4.2 *Role of Instrument Response*

Equations (35–37) show that the instrument response function, $R(\tilde{\nu})$, has an impact on the appearance of single-beam emission spectra. Consequently, $R(\tilde{\nu})$ can be determined experimentally by comparing the emission spectrum of a good laboratory blackbody to

Figure 7 Emittance spectra of PMMA film using an mercury cadmium telluride (MCT) detector: (a) with background correction, and (b) without background correction. (Reproduced by permission of the Society of Applied Spectroscopy from Chase, *Appl. Spectrosc.*, **35**, 77–81 (1981).[8])

the appropriate Planck functions. For instance, using a room-temperature detector, stray radiation of the room-temperature surroundings (background) can be neglected, and $R(\tilde{\nu})$ can be obtained from Equation (37) as follows, from Equation (39):

$$R(\tilde{\nu}) = \frac{L_{bb}(\tilde{\nu}, T_i, T_d)}{[H(\tilde{\nu}, T_i) - H(\tilde{\nu}, T_d)]} \quad (39)$$

i.e. as the ratio of the measured single-beam blackbody spectrum to the difference of two theoretical blackbody emission curves corresponding to the temperature of the sample and the detector, respectively. $R(\tilde{\nu})$ is expected to be independent of sample temperature but the precision of its determination is the higher, the greater the temperature difference.

The explicit knowledge of $R(\tilde{\nu})$ is not necessary when working with double-beam emittance spectra, but it may prove very useful in several other applications:

- Blackbody reference spectra can be simulated for any desired temperature by multiplying $R(\tilde{\nu})$ with the corresponding Planck function, which can save time by eliminating a great number of reference measurements;
- Single-beam emission spectra can be corrected for instrumental distortions if they are divided by $R(\tilde{\nu})$;
- If the temperature of a blackbody radiator is to be determined, before fitting the Planck functions to the measured single-beam spectra they must be corrected for detector temperature and instrument response.[9]

2.4.3 *Effect of Sample Temperature*

In order to be detected, the radiating sample may be warmer or cooler than the detector (Figure 8), i.e. in the absence of a temperature difference there is no signal (no interferogram in case of an FTIR measurement). The signal appears when $\Delta T = T_s - T_d > 0$ and it grows with increasing ΔT. (The sign of the temperature difference is not reflected in the single-beam spectrum, but the interferogram gets inverted when ΔT is negative.)

The temperature dependence of single-beam spectra originates from the temperature dependence of the Planck function (see Equation 18 and Figure 3), which is reflected also in the Stefan–Boltzmann law (Equation 10). It is anticipated that owing to this very strong temperature dependence of the intensity of single-beam emission spectra, the sample temperature must be strictly controlled and held constant during data acquisition.

Band intensities in double-beam emission spectra do not show temperature dependence (see Figure 8), unless chemical or structural modifications take place.[8] This follows from theory: when ratioing the single-beam emission spectrum of the sample to that of the blackbody (measured at the sample temperature), the factors depending on temperature will be eliminated. Nonetheless, any temperature mismatch between sample and reference (blackbody) will show up in the spectrum

Figure 8 Emittance spectra of a polystyrene film: (a) at 40 °C and (b) at 10 °C (with the detector at 25 °C). (Reproduced by permission of the Society of Applied Spectroscopy from Chase, *Appl. Spectrosc.*, **35**, 77–81 (1981).[8])

Figure 9 Relative sensitivity of FTIR emission measurements done with sample temperatures 60, 120, 180 and 400 °C compared to an absorption FTIR measurement.

in the form of curved backgrounds and altered relative band intensities.

Note also that an emittance spectrum measured at a higher temperature will have a higher S/N (meaning higher sensitivity) due to the greater amount of energy available for the two single-beam measurements involved. In this context it is interesting to compare the sensitivity of the IR emission measurement to that of IR absorption. In theory, the sensitivity of the two techniques (with the same instrument) depends on the temperatures of the emitters of the blackbody source used for emittance measurements and the Globar source used for absorption measurement.[12] The relative sensitivity curves shown in Figure 9 were obtained with Planck functions with a Globar source temperature taken as 1500 K and blackbody sample temperatures 60, 120, and 180 °C, commonly used in laboratory measurements. The curves clearly show the strong decrease in sensitivity of IRES toward higher wavenumbers, which manifests itself as increased noise level in the region above 3000 cm^{-1} (this is seen in Figure 6c). In order to have good S/N in this region, the sample temperature should be increased to about 400 °C.

2.4.4 Effect of Sample Thickness

The thickness of condensed-phase samples is a critical parameter in IRES when conventional methods of thermal excitation are used (samples in thermal equilibrium and no temperature gradient across the sample). Theory and practice have shown that the ideal sample thickness for IR emission spectroscopy is the same as for IR absorption spectroscopy, i.e. 1–5 µm. With the increase of sample thickness, the intensities of emission bands will increase and broaden gradually, so that spectral contrast gets worse and worse (see the lower

Figure 10 Emittance spectra of 2.5, 9 and 100 µm thick poly(ethylene terephthalate) (PET) films compared to the reflectance spectrum of PET. Note the correspondence between reduced emission of the 100 µm film and the reflectance features. (Reproduced by permission of the Society of Photo-Optical Instrumentation Engineers from Willis, Sheppard and Chalmers.[18])

three traces in Figure 10). Excessive thickness makes the sample opaque (nontransparent) when the single-beam emission spectrum of a semitransparent material becomes continuous like that of the blackbody. In this case the emission spectrum is no longer characteristic of the material and depends mainly on the temperature of the sample.

The quantitative relationship (Equation 40) between thickness and sample emittance is given by the emission spectroscopic equivalent of the Lambert–Beer law (valid if Equation 32 holds):

$$\varepsilon(\tilde{\nu}) = 1 - \tau(\tilde{\nu}) = 1 - 10^{-K(\tilde{\nu})d} \qquad (40)$$

where $K(\tilde{\nu})$ is the linear decadic absorption coefficient of the material and d is the layer thickness; for solutions or gas mixtures $K(\tilde{\nu})$ is replaced by $b(\tilde{\nu}) \times c$, where b stands

for the molar decadic absorption coefficient (usually also denoted by ε), and c is concentration. The connection to the absorbance of the sample, $A(\tilde{\nu})$, which is the linear intensity scale used in absorption spectrometry, is given by Equation (41):

$$A(\tilde{\nu}) = K(\tilde{\nu}) \times d = -\log[1 - \varepsilon(\tilde{\nu})] \tag{41}$$

2.4.5 *Problems Expected with Condensed-phase Samples*

An emission experiment, in fact, differs from the simple transmission–reflection model depicted in Figure 5(a) in that the emitted radiation originates within the sample and goes in every direction in space, but we observe only radiation emerging from a given direction within a certain solid angle, as shown in Figure 5(b). Several papers have dealt with theoretical models and suggested approximate expressions for the emittance of semitransparent condensed-phase samples under various sampling conditions.[13–17] Single and multiple layers of samples have been considered in different arrangements, e.g. between IR transmitting windows, between a reflecting metal back-plate and a window, or on a back-plate but without a window, etc. These treatments are based on ray tracing and energy conservation at all interfaces while considering the optical properties of the materials: internal transmittance and possible reflections at the interfaces.

Perhaps the most comprehensive treatment can be found in the publications by Hvistendahl et al.[15] and Rytter[16] who have also pointed out some errors in earlier publications. For a simple case that is often used in practice, an uncovered layer of liquid or solid sample on a perfectly reflecting back-plate support, the emittance can be expressed (Equation 42) through the internal transmittance of the sample (τ), and its reflectance at the front surface (ρ) as

$$\varepsilon = \frac{(1 - \rho)(1 - \tau^2)}{1 - \rho\tau^2} \tag{42}$$

which refers to double pass of the emitted radiation through the layer (compare with the basic Equation 30). For detailed results concerning multilayered samples or other methods of observation, the original papers should be consulted.[15,16]

2.4.6 *Reduced Emission Phenomena: Surface Reflectivity and Self-absorption*

In case of measurements of solids and liquids, irregular or distorted band shapes are often observed, especially for strong bands near their peaks. This is usually referred to as reduced emission phenomena.[17] In addition to reduced relative band intensities as compared to those observed in the absorption (transmittance) spectrum, some part of the band peak seems to be missing, leading to inversion of the peak and apparent splitting of the band. This can be seen on the spectra of the thick samples in Figure 10.[18] Two explanations have been put forward to explain this phenomenon: surface reflectivity and self-absorption.

It has been shown,[15,16] that surface reflectivity appearing in the expressions of sample emittance (e.g. in Equation 30) may be responsible for such distortions because of variations (sudden increase and decrease) of reflectivity in the vicinity of strong absorption bands, which cannot be neglected. These authors have used the damped harmonic oscillator model to simulate this phenomenon (see Figure 11a and b), and have shown that surface reflectivity leads to asymmetric distortion of strong emission bands.

A simple and effective practical method has been proposed to eliminate this kind of distortion:[15] to use, instead of a laboratory blackbody as reference, a sufficiently thick, opaque sample (for which $\tau = 0$) of the same material as the sample. The quantity obtained this way (Equation 43):

$$\varepsilon_s^* = \frac{L_s}{L_{op}} = \frac{\varepsilon_s}{\varepsilon_{op}} \tag{43}$$

is referred to as emittance with an opaque sample as reference. Since the thin and thick samples have approximately the same surface reflectivity, this procedure diminishes its influence and distortion-free emittance spectra can be obtained. (See an example in Figure 11c and d.)

Griffiths[12] attributed some reduced emission phenomena to self-absorption, i.e. to reabsorption of radiation originating in the bulk of the sample by the colder surface layer. This can also be verified theoretically using similar spectral simulations[10,16] as above leading to Equations (44) and (45):

$$\varepsilon(\tilde{\nu}) = (1 - \tau_b)\tau_s \tag{44}$$

or

$$\varepsilon(\tilde{\nu}) = (1 - \tau_b^2)\tau_s \tag{45}$$

corresponding to emitting samples without or with a reflecting back-plate, respectively, where τ_b and τ_s are transmittances of the bulk and surface layer, respectively, depending on the respective thicknesses (d) as Equation (46):

$$\tau(\tilde{\nu}) = 10^{-K(\tilde{\nu})d} \tag{46}$$

Calculations show (see Figure 12) that self-absorption can lead to band splitting for strong absorptions of thin layers and also for weaker absorptions of thick

Figure 11 Effect of surface reflectivity on emission bands at increasing sample thickness: (a) Calculated band profiles for the case of reflecting backplate and sample without window, and (b) the same with a transparent window over the sample. (c) Emittance spectra of very thin (lower trace), intermediate (middle trace) and very thick, opaque (upper trace) Al_2Cl_6 samples measured at 200 °C with blackbody reference, and (d) emittance spectra of the same very thin (lower trace) and intermediate (upper trace) Al_2Cl_6 samples with the use of the opaque sample as reference. (Reproduced by permission of the Society for Applied Spectroscopy from Hvistendahl, Rytter, Oye, *Appl. Spectrosc.*, **37**, 182–187 (1983).[15])

layers, and this effect leads to symmetric splitting of strong absorption bands, which allows it to be distinguished from surface reflectivity.[16] Heating the sample from the front is expected to diminish self-absorption.

2.4.7 Sample Orientation and Metal Surface Effects

In the preceding discussion the emitted radiation has been assumed to be homogeneous and unpolarized under any viewing angle, which is correct for gas

Figure 12 Simulation of the effect of self-absorption by a cooler surface layer (d_b and d_s are thicknesses of the emitting bulk and absorbing surface layers, respectively). (Reprinted with permission from Keresztury, Mink, Kristóf, *Anal. Chem.*, **67**(20), 3782–3787 (1995).[10] © 1995 American Chemical Society.)

phase work and for most condensed-phase samples. However, if the sample shows macroscopic order such that the molecules are oriented or aligned about a distinguished direction (which occurs, for instance, in oriented crystalline layers or stretched polymer films), the transition dipole moments associated with vibrational transitions also assume preferred directions in space. In this case the radiation is strongest in the plane perpendicular to the transition dipole, and is polarized in the plane defined by the propagation direction and the transition dipole.

Another practically important case is when the emitting molecules are located near a metal surface. When the distance between the surface and the molecules is very small compared to the wavelength of the emitted radiation (e.g. as in the case of adsorbed molecules), special selection rules apply, known as metal surface selection rules. Greenler[19] has calculated the angular intensity distribution of light emitted by radiating dipoles that

Figure 13 Calculated angular intensity distribution of emission by a dipole oriented perpendicularly to the metal surface (the emission angle is measured from the normal to the surface). (Reprinted from Greenler, 'Light Emitted from Molecules Adsorbed on a Metal Surface', *Surface Science*, **69**, 647–652 © (1977) with permission from Elsevier Science.[19])

are parallel and perpendicular to the metal surface. His results indicate that

1. one should not expect to see IR emission from molecular vibrations whose transition moments are parallel to the surface;
2. for vibrations with transition moments perpendicular to the metal surface, the best viewing angle is 70° to 80° from the surface normal and the radiation is polarized parallel to the plane of incidence, while in the direction perpendicular to the metal surface the emission intensity is zero (see Figure 13).

These selection rules help in determining the orientation of molecules on the surface and have to be taken into account when setting up such an experiment. For instance, part of the unpolarized background radiation can be eliminated and the S/N can be substantially increased by inserting an IR polarizer into the beam or by using a polarization-modulation technique.[20]

3 INSTRUMENTATION: SPECTROMETERS AND DETECTORS

Laboratory measurements in IRES can be performed with commercial IR spectrometers designed for absorption measurements to be done in the transmission regime. Some of these instruments have a provision to switch over to emission mode, or at least have an emission port on the instrument housing that can accept an auxiliary emission accessory.

Commercial IR spectrometers can be divided into two broad classes: dispersive (prism or grating) instruments and FT (or interferometric) instruments. Dispersive instruments dominated IR spectroscopy from the early days of its history until the end of the 1970s, when FTIR instruments started proliferating at a great pace, together with fast digital data handling facilities.

Both dispersive and FTIR instruments are mechanical-optical devices that have the following main components:

- incandescent IR radiation source (switched off or replaced by the sample in IRES);
- a dispersion element (in the dispersive instruments) or an interferometer (in the FTIR instruments);
- an IR detector (with amplifier electronics);
- a device for recording (plotting or storing) the measured data.

The first three components are connected by optical elements (mostly mirrors) that direct, collimate or focus the light as appropriate. The radiation source and the detector are in the two terminal focal points of the spectrometer optics. The peculiarity of emission measurements is that the sample itself serves as the source of radiation; thus the sample replaces the usual light source or it is put at an optically equivalent location inside or outside the spectrometer cover (by an auxiliary port), and the conventional sample compartment remains empty.

3.1 Dispersive Instruments

Conceptually, the dispersive instruments are much simpler, since they measure the spectrum directly. The IR beam to be analyzed is dispersed by a prism or more commonly by a diffraction grating to spatially separate the different wavenumber components, and the optical image of the spectrum is scanned through with a narrow slit permitting only energy from a narrow spectral interval to fall on the detector. During the scan, the intensity of the radiation is recorded as a function of wavenumber.

To suit the requirements of the much more commonly used transmission spectrometry, most dispersive IR spectrometers are built as double-beam instruments with optical-null or ratio-recording detection[21] (shown schematically in Figure 14). Their working principle is as

Figure 14 Optical scheme of a double-beam dispersive IR spectrometer. (PM, paraboloid mirror; EM, ellipsoid mirror.)

follows: the radiation emitted by the IR source is divided by symmetrically arranged mirrors into two equivalent beams, the sample beam and the reference beam, both passing through the sample compartment next to each other. The beams are focused on the entrance slits of the monochromator and are combined by means of a rotating chopper into one common path, letting the alternating sample and reference beams fall on the dispersing element, then through the exit slit of the monochromator on the detector. The spectrum is recorded in real time (during scanning) as the ratio of the sample beam intensity (I) to the reference beam intensity (I_0).

In a transmission measurement the emitter is an incandescent light source operating at above 1000 K (such as a Globar or a nichrome filament); from its radiation the sample is supposed to absorb more energy than the reference, thus the recorded intensity ratio gives the transmittance of the sample relative to that of the reference: $\tau(\tilde{\nu}) = I(\tilde{\nu})/I_0(\tilde{\nu})$.

In contrast, in an emission measurement the standard light source of the instrument is switched off or removed and the emitting sample and a reference emitter (a laboratory blackbody) are put in its place or at optically equivalent positions. Usually some modification of the source optics is needed to accommodate both emitters in the focus of the respective paths on a joint, heated (temperature controlled) sample stage. In principle, both emitters can be put in the sample compartment as well, but then special light-gathering optics are needed to increase the throughput of the emitted radiation to the detector. Various double-beam or semi-double-beam emission source arrangements have been discussed in Huong's review.[4] The recorded intensity ratio, in this case, directly gives the emittance of the sample, $\varepsilon_s(\tilde{\nu})$, i.e. its emission intensity relative to that of the blackbody at the same temperature in accordance with Equation (26).

Although the emittance spectrum can be directly measured with a double-beam grating spectrometer, these instruments are rarely used today in emission spectroscopy, partly because of the overwhelming technical advantages of FTIR instruments for detection of weak signals, and also because two costly emission attachments are needed.

3.2 Fourier Transform Infrared Instruments

FTIR spectrometers measure single-beam spectra (or rather interferograms corresponding to single-beam spectra) directly, thus the method by which emittance spectra are obtained is quite different from the way they are measured on a double-beam grating spectrometer. The usual procedure of measuring $\varepsilon_s(\tilde{\nu})$ on an FTIR spectrometer is to measure the reference (e.g. blackbody) interferogram first, store the

measured data in the memory of the computer and calculate the single-beam reference spectrum; the sample is then inserted in the emission accessory and the same operations are done with the sample to obtain its single-beam spectrum. Finally, the desired double-beam spectrum (the emittance spectrum) is calculated as a point-by-point ratio of the two single-beam spectra.

The schematic optical layout of an FTIR spectrometer equipped with an auxiliary emission accessory is shown in Figure 15. The heart of an FTIR spectrometer is the Michelson interferometer consisting of a beamsplitter and two mutually perpendicular mirrors, one fixed and the other moving back and forth at a constant velocity. The collimated IR radiation enters the interferometer and falls on the beamsplitter (a semitransparent, semireflecting material) at 45° where it is divided into two equal parts and travels towards the two mirrors. The reflected beams returning from the fixed and moving mirrors with changing path difference are combined together at the beamsplitter where they interfere with one another. This interference causes variations in the instantaneous intensity of the beam that is focused on the detector. The measured intensity, $I(\delta)$, of the modulated beam as a function of optical path difference, δ, in the two arms of the interferometer is called the interferogram; it contains multiplex information from all spectral elements in each data point. The interferogram, $I(\delta)$, and the single-beam spectrum, $L(\tilde{\nu})$, are FT pairs, thus the spectrum is obtained from the digitized interferogram by Fourier transformation (Equation 47):

$$L(\tilde{\nu}) = \int_{-\infty}^{\infty} I(\delta) \times \cos 2\pi\tilde{\nu}\delta \times \mathrm{d}\delta \qquad (47)$$

For a most comprehensive description of the theory and a wide range of practical aspects of FTIR spectrometry the reader is referred to the monograph written by Griffiths and deHaseth.[12]

Figure 15 Optical scheme of an FTIR spectrometer equipped with an auxiliary emission compartment. (PM, paraboloid mirror; MM, moving mirror; M, fixed mirror; EM, ellipsoid mirror; BS, beamsplitter.)

With an FTIR instrument, other optical arrangements are also possible, e.g. the radiating sample could replace the detector when an auxiliary detector is used, but this is rarely a practical solution. For versatility it is essential that the instrument be equipped with an emission port easily accessible through a flip mirror to accept light from an auxiliary emission attachment.

3.1.1 Advantages of the Fourier Transform Infrared Technique

For all the complexity of its operation principle, the interferometric measurement technique offers several advantages compared with conventional dispersion IR spectroscopy.

Higher Signal-to-noise Ratio Under conditions of equal measurement time, FTIR spectra show higher S/N. This is the consequence of two factors:

1. the higher optical throughput of the interferometer than that of a grating monochromator (a factor of 50 to 200, due to elimination of the narrow optical slits);
2. the so-called multiplex advantage arising from the fact that in FTIR all of the spectral elements are observed for the whole measurement time, while in a grating instrument the measurement time has to be divided by the number of resolution elements in the whole spectrum. For the whole IR region at a resolution of 4 to $1\,\mathrm{cm}^{-1}$ this gives a gain factor of 30 to 60 in S/N, and even more at higher resolutions. Higher S/N means higher sensitivity, which is essential in IRES measurements, especially when the temperature difference between sample and detector is relatively small and low radiation levels have to be measured.

Greater Frequency Accuracy The interferometers of FTIR instruments have a built-in visible laser reference to control the mirror movement, which helps determine the wavenumber scale of the spectrum with very high accuracy (no additional wavenumber calibration is needed except for high-resolution spectra).

Computerized Data Handling Computerized data handling is not limited to FTIR systems but because of the need to store the measured data in digital form and to perform the Fourier transformation and other necessary calculations before the spectrum is obtained, FTIR spectrometers are ab ovo equipped with dedicated microcomputers or are connected to PCs and work under computer control. The instrument manufacturers supply

proprietary software with the instrument for data acquisition and analysis, which may incorporate interactive tutorials and integrated diagnostics packages as well.

Based on the above advantages, FTIR spectrometers as of today are preferred to dispersive machines in most IRES applications. There are more than half a dozen well-known instrument manufacturers in the market offering good-performance FTIR instruments in a broad price range (from $30 000 to $150 000) that are meant basically for transmission work. The cheaper models may be adequate for routine laboratory measurements to obtain qualitative data at low spectral resolution (max. 1 cm^{-1}), and are usually limited to the 4000 to 400 cm^{-1} spectral range. The more expensive ones are supposed to have a higher-quality interferometer (featuring dynamic alignment, possible step-scan operation) suitable for higher-resolution work (at least 0.1 cm^{-1}), and be more versatile, offering a choice of built-in interchangeable components, e.g. different detectors, beamsplitters and sources to cover the entire spectrum from the FIR to the NIR. While faster scanning instruments with high optical throughput are always preferred for IRES, high resolution is needed only for gas-phase work, for sure identification of unexpected species with resolvable rotational fine structure. Lower-resolution spectra with higher S/N are more useful in most quantitative applications than highly resolved but noisy spectra.

3.3 Open-path Fourier Transform Infrared Instruments

One of the natural applications of IRES, remote sensing, stems from its single-ended measurement geometry allowing the observation of spectra of thermal emitters located at a distance from the instrument. Since atmospheric or environmental studies of emission sources most often involve field measurements, the instruments used must be mobile, i.e. mounted on a vehicle, or be compact and lightweight to be carried more easily. For this purpose dedicated open-path Fourier transform infrared (OP/FTIR) spectrometers are used that are equipped with a telescope to collect the radiation and matched transfer optics to pass a collimated beam into the interferometer.

One of the most popular designs consists of a 25-cm Newtonian telescope and a standard Michelson interferometer with a liquid-nitrogen-cooled MCT detector. A simplified optical diagram of such an instrument is shown in Figure 16. The spectrometer is mounted on the top of the telescope barrel making a very compact structure that can be set up on a tripod stand to point it conveniently toward the remote source. The instrument can run on battery power and may be controlled by a portable laptop computer in remote locations. Other OP/FTIR spectrometers may incorporate a Cassegrain-type telescope, a more

Figure 16 Optical scheme of an open-path FTIR spectrometer with a Newtonian receiver telescope. (PM, paraboloid mirror; M, mirror.)

sensitive liquid-helium-cooled detector (especially for the FIR region, in high altitude and extraterrestrial measurements), and provision for measurement of blackbody reference spectra or calibration standards for quantitative analysis. With the addition of a portable artificial IR source (equipped with a source telescope) or a remote cube-corner array retro-reflector, these instruments can also work in transmission mode. A famous early mobile remote sensing FTIR instrument built for the United States Environmental Protection Agency (USEPA) in the 1970s around a commercial, moderately high resolution FTIR system configured to fit into a van, the so-called Remote Optical Sensing of Emissions (ROSE) system, has been described together with some of the measurement results.[22]

Obtaining the appropriate blackbody reference spectrum may pose some problem, since in the case of remote natural sources of radiation the temperature of the source may not a priori be known. Knowledge of the instrument response in this case may prove useful, since it allows easy simulation of single-beam blackbody reference spectra from Planck functions for various temperatures (see section 2.4). After dividing the sample spectrum by the trial reference spectra, the one giving a double-beam (emittance) spectrum with the flattest background will correspond to the right temperature.

A serious limiting factor of the applicability of IRES in environmental or remote atmospheric measurements (e.g. the measurement of the plume of a power plant smokestack or hot gases from combustion jets) is atmospheric absorption. Since there is a great absorbing pathlength (typically from several meters to about a kilometer) between the remote source and the spectrometer, atmospheric water vapor and CO_2 may completely block certain spectral regions, prohibiting the detection of some pollutants.

3.4 Choice of Detectors

The description of IR detectors is beyond the scope of this article, but one should be aware of how an emission measurement is affected by the type of detector used, and choose the detector or treat the data accordingly.

There are two basic types of IR detectors: room temperature pyroelectric detectors and cooled quantum detectors. To a first approximation a detector can be characterized by its operating range and its specific detectivity, D^*,[12] which depends on wavenumber. Broad-range detectors that can be used in the whole IR region are less sensitive than narrow-range detectors. The most commonly used room-temperature detectors are triglycine sulfate (TGS) and DTGS, the latter being several times more sensitive in the whole IR region. The most popular cooled, broad-range detector is the photoconductive MCT detector (MCT, HgCdTe) operating at liquid-nitrogen temperature (77 K). The MCT detector is by more than an order of magnitude more sensitive than DTGS and its response to the changing signal is also incomparably faster, allowing the measurement rate to be increased to 5–10 interferogram scans per second (depending on resolution). Higher sensitivity detectors are available for narrower spectral regions (some may require cooling below 20 K with liquid helium); for example the InSb detector has nearly unit quantum efficiency but it does not work below 1800 cm^{-1}.

Based on the above properties, the cooled MCT detector could be preferred in IRES to compensate for the usually low signal level. In addition, heat radiation leaving the detector at 77 K is negligible, which means that in this way practically the full sample emission is detected (see Equations 35 and 36 and the discussion in section 2.4), even if it is not heated. One should not forget, however, that an MCT or other low-temperature detector will detect, in addition to sample emission, thermal radiation of all room-temperature objects in its field of view, including parts of the instrument itself, (e.g. the beamsplitter).[11] Thus, with the choice of an MCT detector comes the obligation of making a correction for background radiation with the extra measurements involved, according to Equation (38).

In contrast, with the use of a DTGS detector, the sample must be kept at a temperature higher (or lower) than room temperature to get appreciable radiation flux. But although the single-beam spectrum may not be as intense (the S/N may not be as high) as with an MCT detector, the spectra obtained are usually free from spurious bands. For this reason, a room-temperature DTGS detector may be a better choice for routine IRES applications.

3.5 Custom-built Instruments for Special Applications

While commercial instruments with matched sample optics are suitable for most IRES experiments, important research fields such as the study of adsorbed species on metal single crystal surfaces or IR chemiluminescence have more stringent requirements owing to the extremely low emitted signal levels. Because of the latter, liquid-helium-cooled detectors have to be used when the sample is kept at room temperature, but then precautions must be taken to minimize background radiation.

Durana et al.[23] have solved this problem by utilizing a cryogenically cooled FTIR spectrometer, by immersing a Michelson interferometer designed to operate at 77 K into a cold helium-purged chamber and cooling the whole optical collection system to 77 K. The equipment shown schematically in Figure 17 was equipped with a liquid-helium-cooled photoconductive Ge/Cu detector and with a gold/KRS-5 wire grid polarizer inserted into the collection beam. The samples (e.g. molecular monolayers adsorbed on metal single crystal surfaces) were maintained at a temperature between 80 and 500 ± 1 K and tilted to give an angle of incidence of 50–55° to approach the optimum

experimental conditions predicted by Greenler[19] (see section 2.4). A similar type of cryogenic interferometer system has been used previously to carry out high-sensitivity gas-phase studies of IR chemiluminescence.[24] The working ranges of these instruments were 2000–1250 and 2000–720 cm^{-1}.

Another cryogenic spectrometer based on Czerny–Turner-type grating spectrometer (see Figure 18) was described by Richards et al.[25] and used successfully in a series of studies of weak low-frequency adsorbate–substrate vibrations on clean, metal single crystal samples. In this case the whole spectrometer was cooled with liquid helium to 4.2 K, and was connected to an ultrahigh vacuum system sharing the sample compartment with other surface analysis methods. One advantage of this instrument over the cooled FTIR systems introduced above is the broader useful spectral range extending down to 330 cm^{-1}. The authors claim that the S/N attainable with this instrument in this particular application is comparable to that of an FTIR instrument, and the grating instrument is easier to cool. Anyhow, one tends to share the opinion[8] that this instrumental modification is really not viable for routine analytical applications.

4 LABORATORY METHODS

4.1 Conventional Methods of Thermal Excitation

As it has been mentioned above, IR detectors respond to any deviation from radiation balance between sample and detector. This means that the sample (or more precisely, the portion of sample in the field of view of the detector) must be either at a higher or at a lower temperature than the detector.

In conventional thermal emission spectroscopy the samples are heated to above room temperature and are kept at constant temperature (in thermal equilibrium) during the measurement. Various types of high-temperature or variable-temperature cells have been designed for IR transmission work,[26] and in principle all these can also be used in IRES. Genuine emission cells, however, have a metal body (made of highly reflecting, low-emissivity material) and are backed with a reflector plate which, in addition to blocking the outside radiation, brings a twofold gain in emission intensity. The shiny metal backplate (polished stainless steel or gold-covered copper block) often serves also as a heater for liquid and solid films. Temperature feedback to the controller is provided by a thermocouple mounted in a hole drilled in the heater block.

4.1.1 Methods for Gases

The measurement of IR emission spectra of hot gases poses little problem experimentally. The temperature in this case may be high enough to produce intense spectral features, and the bands show rotational structure consisting of series of very narrow lines that are easy to identify using high resolution (at least 0.1 cm^{-1}). Also, there are no surface effects that could distort the spectral features. The pathlength requirements of the gas samples are not so stringent either as with condensed-phase

samples: pathlengths of a few millimeters to hundreds of meters or even kilometers (in case of open-path instruments) may be acceptable depending on the partial pressure of the gas.

Laboratory measurements of emission spectra of gases often serve for calibration purposes, as reference for remote sensing by IRES. These calibration spectra must be measured at known (controlled) pressure, temperature and pathlength, but may be obtained either in emission or in transmission mode, then converted to absorbance scale. For IRES measurements, the standard single-pass or multipass transmission gas cells[26] surrounded with a cylindrical oven can be used (e.g. a 10-cm cylindrical Pyrex cell with KBr windows), although in this case higher background emission is expected than with a metal tube surface. Limiting the field of view with cold (water-cooled) apertures may help improve the S/N.

The potential of FTIR emission spectroscopy for the study of gas-phase molecules has been reviewed recently by Bernath.[27]

4.1.2 Methods for Liquids

Again, conventional heated liquid transmission cells can be easily converted to emission cells by replacing one of the two parallel windows by the heatable reflecting back plate. As a horizontal liquid sample holder, flat-bottomed shallow metal cups can also be used, in good thermal contact with a heater stage (Figure 19). In horizontal liquid sample holders the top window may be omitted, although a windowed cell has some advantages:[16] the sample may be compressed to a thin film between the window and the support, evaporation is minimized and a uniform sample temperature is assured with a window of high thermal conductivity, which may also minimize cooling of the surface and occurrence of self-absorption.

Figure 19 Cross-sectional view of a typical emission accessory for solids and liquids with exchangeable sample holder and collection optics.

4.1.3 Methods for Solids

The most widely proliferated method is to put the sample in direct contact with an electrically heated metal block when the sample is heated from the reverse side (not facing the spectrometer). A circular, heatable metal stage of about 10–15 mm diameter may serve as a good solid sample holder, e.g. in an emission accessory shown in Figure 19. This configuration has the disadvantage that the front surface of the sample may be somewhat cooler than the bulk and reabsorption of the emitted radiation may occur, leading to distortions and splitting of emission bands as described earlier.

Horizontal sample stages are more practical in case of some solid samples, as well: they hold polycrystalline or powdered samples more easily than vertical or tilted sample holders. Good adhesion to the support for better heat transfer may be facilitated by depositing the sample on the support from solution or suspension by slow evaporation of the solvent. The optimum amount of sample to deposit is around $0.1\,\mathrm{mg\,cm^{-2}}$. Unless the sample is too thick, a useful emission spectrum can be obtained from uneven layers or chunky materials as well, but the spectral contrast may deteriorate considerably compared to the spectra of even and smooth emitting layers. For polymer films or other smooth layers of neat materials the ideal sample thickness is in the range of 1–5 μm.

Microreactor-type sample cells have also been built, for example for in situ studies of heterogeneous catalytic reactions.[28] They are based on quartz, Pyrex glass or stainless steel chambers that withstand high temperatures, can be evacuated or placed under pressure, and purged with gases as necessary and are equipped with the usual heating and temperature controlling facilities. A typical catalytic microreactor design is shown in Figure 20.

4.1.4 Samples at Ambient or Low Temperatures

There are several ways to avoid cooling of the front surface. Naturally, it should not occur with the use of a

Figure 20 Cross-section of a catalytic microreactor-type emission accessory.

cooled detector if the sample is kept at ambient temperature, or with the use of a room-temperature detector if the sample is cooled. Under these circumstances, however, the measurement is practically restricted to the spectral region below 2000 cm^{-1} because the maximum of available energy will be that of a 300 K blackbody (see Figure 3), and the signal, if any, would hardly exceed noise level at higher frequencies.

4.1.5 Laboratory Blackbody Sources

There is a great variety of so-called laboratory blackbody emission sources used to provide a reference or calibration standard for thermal emission measurements. A heated black-walled cavity with an aperture makes a good approximation to an ideal thermal emitter (with emittance close to 0.99), and commercial blackbody calibration sources are of this type. These devices have precise temperature control (some of them up to 3000 K) but since they are usually too large to fit into most emission accessories designed for microsamples, they are used mostly in gas-phase work and remote sensing.

With condensed-phase samples, it is desirable also that exactly the same optical arrangement be used with the same heater and temperature controller settings in both sample and reference measurements. Thus, perhaps the most convenient choice in practice is to use a metal plate covered with a thick layer of heat-resistant matt-black paint; but there are some other suitable black materials such as a sooted metal disc or aluminum foil, a graphite disc or a layer of carbon black on the standard sample stage. One should keep in mind, however, that the emittance of these laboratory blackbodies may not exceed 0.9.

4.1.6 Emission Accessories

An emission accessory consists of a controlled-temperature sample cell placed in the focus of a light collection optics (normally an off-axis ellipsoid or off-axis paraboloid mirror) that sends the radiation into the spectrometer. Ideally, the cell is mounted on a three-dimensional (3-D) translation stage to facilitate sample alignment. Solid sample holders may require a tilting facility. A sketch of a typical emission accessory is shown in Figure 11. A version of this accessory incorporates a microscope mounted in the collecting mirror to help locate the area of interest on the sample surface.[29] Further modifications have been described to improve the sample temperature stability to permit the acquisition of quantitative IR emission data.[30]

4.2 Advanced Methods for Solids

The greatest challenge of IRES is to obtain meaningful spectra (having vibrational structure) of thick, opaque solid samples. We have seen that conventional thermal excitation by heating the sample from the rear is unable to solve this problem. However, heating of the sample can be accomplished by various means from the front, as well. In addition, by simultaneous heating and cooling of different points of the sample, temperature gradients can be maintained or generated temporarily or periodically along the thickness of the sample, which creates favorable conditions for observation of emission from a thin surface layer. Thus, irradiation of the front surface with laser beams, both visible and NIR, pulsed or continuous wave, and also blowing the surface with a stream of hot air have been tested.

4.2.1 Laser-induced Thermal Emission

One of the recent developments is laser-induced thermal emission spectroscopy (LITES).[31,32] Results of the preliminary investigations in LITES have shown that it is a feasible approach because heat generation via absorption of laser light by the sample is more or less localized on its surface, regardless of the thickness, shape and composition of the sample or the support material. This means that sample thickness is no longer a limiting factor, i.e. emission spectra of the surface layers of thick samples or objects of any dimensions can be measured. However, the efficiency of this method depends on the absorptivity of the sample at the laser wavelength. Thus, for some samples (e.g. red paint) the 514.5 nm green line of an Ar-laser may be quite efficient[32] while in general a NIR neodymium yttrium aluminum garnet (Nd/YAG) laser is thought to be a better choice.[31]

4.2.2 Methods of Transient Heating

Excitation of thermal emission of the surface layer by a continuous-wave laser is not without difficulties because owing to thermal diffusion the thickness of the heated emitting layer increases with time, which causes a gradual deterioration of spectral contrast. This effect can be reduced by various regimes of transient or modulated heating. Fully successful LITES experiments have been described[33] with the use of the experimental set-up shown in Figure 21 where heat build-up in the sample is prevented with a cooling gas jet directed next to the heated spot on a rotating sample. Under such conditions a transiently heated thin surface layer is generated in the sample, and it is only the emission of this surface layer that is detected. If instead of a continuous laser a pulsed laser is used in conjunction with a rotating sample, the cooling gas jet can be omitted.[34]

A much more economical but similarly successful version of the transient-heating method uses a hot-gas jet in place of a laser to heat the surface of the sample (Figure 22).[35] This heat source combined with a rotating

Figure 21 Experimental arrangement used for observing transient infrared emission spectroscopy (TIRES) spectra with laser excitation. (Reprinted with permission from Jones, McClelland, *Anal. Chem.*, **61**, 650–656 (1989).[33] © 1989 American Chemical Society.)

sample and cooling gas jet allows the study of materials that do not absorb strongly at common laser wavelengths.

Figure 23 Comparison of the performance of the TIRES method with that of conventional IRES on an opaque polycarbonate sample. Upper part: single-beam emission spectra; lower part: double-beam emittance spectra compared to photoacoustic absorbance spectra. (Reprinted with permission from Jones, McClelland, *Anal. Chem.*, **62**, 2074–2079 (1990).[35] © 1990 American Chemical Society.)

With these methods, termed TIRES, analytically useful IR emission spectra can be obtained from optically thick samples as well (see Figure 23).

4.2.3 Modulated Heating

Another new method devised for the study of high-opacity, refractory materials is named modulated emission spectroscopy (MES).[36] It uses an argon ion laser as a pump source modulated by a wheel chopper, while the sample sits on a metallic rod immersed in liquid nitrogen. Note that modulated heating (as with pulsed lasers) requires more complex and costly electronics ensuring

the synchronization of signal sampling with the frequency of modulation or laser firing.

The main advantage of the methods outlined above (LITES, TIRES, MES) is the ability to measure emission spectra of thick samples. It is also possible to perform depth probing by changing the heating-and-cooling regime and hence the thermal diffusion length in the sample.

Beside the indisputable advantages of TIRES, it should be mentioned that some uncertainty arises when converting the single-beam emission spectra to the double-beam emittance scale. The problem is that the heating regimes are not exactly identical between different samples or between sample and blackbody reference. The temperature of the emitting layer is not exactly known and hard to reproduce, thus the comparison of emission intensities and the quantitative evaluation of spectra obtained with the TIRES method is not so straightforward.

4.2.4 Transient Cooling and Emission–Absorption Spectra

Self-absorption is usually considered an unwanted phenomenon. There are instances, however, such as multilayer samples or formation of surface species, when weak negative spectral features appear on the background of continuous, blackbody-like emission of the bulk at characteristic frequencies of some surface species. It has been recognized that these features are not always due to surface reflection, but may be due to appearance of absorption bands on the emission continuum of the bulk.[5] In such cases reabsorption of the bulk radiation by the surface species may be a chance to detect surface species on opaque substrates. If the specific application makes it desirable to exploit reabsorption, it can be fostered by cooling the front surface of the hot sample by a stream of cold air or inert gas. This method of measurement, first reported by Jones and McClelland[37] and later augmented with unsteady-state heat-flow calculations and harmonic oscillator modeling,[38] has been dubbed transient infrared transmission spectroscopy (TIRTS) or infrared emission with transient cooling (IRE/TC). It can be considered as the opposite of transient heating TIRES; not surprisingly, the two methods perform very similarly.

There are other instances when the emitting lower layer is not thick enough to be opaque, but a chemically different surface layer appears to absorb at its characteristic frequencies from the emission spectrum of the lower layer in regions of spectral overlap. Such spectra, containing positive and negative bands alike, are hard to interpret by conventional methods. They may be called emission–absorption spectra, and require spectral simulation and modeling to be fully understood.[10]

5 COLLECTION, HANDLING AND PRESENTATION OF SPECTRAL DATA

5.1 Data Acquisition and Reduction

In view of the relatively low signal level of IR emission spectra, high-speed, high-sensitivity FTIR instruments are commonly used in IRES. With these instruments 1 to 10 interferograms can be measured in a second, so in order to increase the S/N it is feasible to accumulate and average several hundred or even several thousand scans (S/N increases as the square-root of the number of scans). Fourier transformation of the final interferogram using the fast Fourier transform (FFT) algorithm[12] of Cooley and Tukey is just a matter of seconds on PCs for spectra at medium resolution ($1-2\,cm^{-1}$). With condensed-phase samples there is usually no need to use higher than $4\,cm^{-1}$ resolution, since the natural band widths are generally much greater, and higher resolution is concomitant with higher noise.

The advanced data-handling software accompanying most commercial FTIR spectrometers allows the smoothing of noisy spectra, the increase of the apparent spectral resolution by deconvolution techniques, the decomposition of overlapping bands, and the plotting of the spectra in any desired format, etc. These possibilities do not exist without a computer being interfaced with the instrument. Emission spectroscopy may require a few special data-processing operations that are not necessarily found in the otherwise user-friendly, menu-driven software of some commercial systems (e.g. the transformation from emittance to absorbance, and the generation of theoretical blackbody emission spectra). Thus it may prove very handy to have access to independent multipurpose spectroscopy software (such as SpectraCalc or GRAMS/32 of Galactic Industries Corporation) or to general purpose data-handling programs (such as the Microcal Origin of Microcal Software, or the Mathlab of The MathLab).

5.2 Presentation of Emission Spectra: Intensity Scales

Sometimes the single-beam spectra are presented as the final result of the measurement. Alternatively they can be converted to double-beam spectra by dividing them by a reference spectrum measured at the same temperature, with the aim of obtaining a uniform intensity scale throughout the whole spectral region of the measurement and of eliminating the instrumental distortion effects. In the IRES literature three kinds of double-beam emission spectra are encountered:[10]

1. relative emittance, ε_s^{rel}, obtained as $L_s(T)/L_0(T)$, i.e. when the sample emission spectrum is divided by the emission spectrum of a reference material other

than a blackbody, for example that of the empty heater stage or backplate, or when the spectrum of the sample, treated in some way, is divided by that of the untreated sample (all measured at the sample temperature);

2. emittance spectrum, ε_s, obtained as $L_s(T)/L_{bb}(T)$ or according to Equation (38);
3. reflection-corrected emittance, ε_s^*, obtained as $L_s(T)/L_{op}(T)$ according to Equation (43).

Of these, relative emittance (1) has the serious disadvantage that it is in an arbitrary intensity scale that can reach very high values with increased noise level. This follows from the fact that the reference spectrum is sometimes very weak, and division with near zero values leads to emittance values with high relative noise.

Emittance spectra (2) or reflection-corrected emittance spectra (3), on the contrary, are standardized in the sense that they have intensity values between 0 and 1 (or 0 and 100%), so they are similar and complementary to transmittance spectra. It is important to understand that none of the above intensity scales are linearly proportional to sample thickness or analyte concentration. Thus spectral manipulations requiring a linear intensity scale (such as subtraction of spectra, multiplication by a constant, etc.) should not be performed with emittance spectra since they lead to spectral distortions (e.g. altered relative intensities, spurious shoulders and splittings) and may falsify the quantitative information contained in them. Transformation to the linear intensity scale, absorbance, can be performed according to Equation (41).

5.3 Quantitative Aspects

As we have seen above, Equations (40) and (41) provide the connection between emittance (ε), transmittance (τ) and the linear intensity scale, absorbance (A). Although Equation (40) containing the decadic (base 10) absorption coefficients is the most frequently used form of the Lambert–Beer law, for the sake of completeness we give here all versions including those written in terms of the napierian (base e) absorption coefficients (Equations 48 and 49):

$$\varepsilon(\tilde{\nu}) = 1 - 10^{-K(\nu)d} = 1 - 10^{-b(\nu)cd} \tag{48}$$

$$\varepsilon(\tilde{\nu}) = 1 - \tau(\tilde{\nu}) = 1 - \exp[-\alpha(\tilde{\nu})d] = 1 - \exp[-\kappa(\tilde{\nu})cd] \tag{49}$$

where $K(\tilde{\nu})$ and $b(\tilde{\nu})$ are the linear and molar decadic absorption coefficients, while $\alpha(\tilde{\nu})$ and $\kappa(\tilde{\nu})$ are the linear and molar napierian absorption coefficients, respectively; d is the sample thickness or pass length, and c is the concentration. The quantities called linear are used in case of neat, condensed-phase samples, and those called molar are used in case of solutions, mixtures or gases.

In case of multicomponent samples the absorbance spectrum can be expressed through the emittance spectra of the components as follows (Equation 50):

$$A(\tilde{\nu}) = -\log[1 - \varepsilon(\tilde{\nu})] = \sum_i^n \varepsilon_i(\tilde{\nu})c_i d \tag{50}$$

where n is the number of components.

Another method increasingly used for qualitative evaluation of single-beam emission or double-beam emittance data directly (without transforming to absorbance scale) is partial least squares (PLS) multivariate calibration.[39,40] With this method in some cases even better precision can be achieved than is possible with the use of a more traditional univariate analysis, especially when one has to deal with overlapping bands belonging to different chemical species.

6 CONCLUSION AND FUTURE PERSPECTIVE

As we have seen, the fundamental principles and governing laws of IRES with thermal excitation are firmly established; the various sources of distorting effects observed in the spectra are well understood and correction methods have been developed. Compared with IRAS, the S/N in an emission experiment is from 0.2 to 2 orders of magnitude smaller; but in principle, IRES should be more sensitive than IRAS, because it measures the neat sample signal instead of the changes in a continuous, high-intensity background created by the light source used in absorption spectroscopy.[27] IRES may live up to these expectations as soon as an IR avalanche detector (the IR analog of a photomultiplier tube) becomes available for the measurement of very low radiation levels.

Nevertheless, the present level of IR technology already makes IRES an attractive and very useful tool that offers solutions to problems in many branches of chemistry and technology. A recent literature survey[41] shows continued interest in application of IRES to very diverse areas such as: remote sensing and open-path atmospheric monitoring, IRES studies of chemical reactions through highly vibrationally excited reaction products, in situ and real-time monitoring of chemical reactions, deposition processes, etc. the study of vibration-rotation bands of stable and transient molecules, photoluminescence and chemiluminescence. An emerging new field of application of the transient IR spectroscopic methods is the determination of chemical and physical properties of solids and viscous liquids in a moving stream.[42] With further advancement this technique can lead to real-time, on-line

process control, e.g. in certain production plants or in waste processors.

ABBREVIATIONS AND ACRONYMS

ADC	Analog-to-Digital Converter
DTGS	Deuterated Triglycine Sulfate
FFT	Fast Fourier Transform
FIR	Far-infrared
FT	Fourier Transform
FTIR	Fourier Transform Infrared
IR	Infrared
IRAS	Infrared Absorption Spectroscopy
IRES	Infrared Emission Spectroscopy
IRE/TC	Infrared Emission with Transient Cooling
LITES	Laser-Induced Thermal Emission Spectroscopy
MCT	Mercury Cadmium Telluride
MES	Modulated Emission Spectroscopy
Nd/YAG	Neodymium Yttrium Aluminum Garnet
NIR	Near-infrared
OP/FTIR	Open-Path Fourier Transform Infrared
PET	Poly(ethylene terephthalate)
PLS	Partial Least Squares
PMMA	Poly(methyl methacrylate)
ROSE	Remote Optical Sensing of Emissions
S/N	Signal-to-noise Ratio
TGS	Triglycine Sulfate
TIRES	Transient Infrared Emission Spectroscopy
TIRTS	Transient Infrared Transmission Spectroscopy
USEPA	United States Environmental Protection Agency
UV	Ultraviolet
3-D	Three-dimensional

Gas chromatography/infrared (GC/IR) spectroscopy coupling combines the separation power of high-resolution gas chromatography (HRGC) to the highly specific identification technique, infrared (IR) spectroscopy, based on the absorption of IR radiation by the molecules. Relying on different molecular properties, IR is an excellent complement to mass spectrometry (MS) in structural analyses. For volatile compounds, the coupling of gas chromatography/mass spectrometry (GC/MS) has been the universal basic technique for a long time. The advantages of Fourier transform infrared spectrometry (FTIRS) allowed the coupling of gas chromatography (GC) to an FTIR (Fourier transform infrared) spectrometer, ending with a powerful tool, gas chromatography/Fourier transform infrared spectrometry (GC/FTIRS). The first device developed to interface a gas chromatograph to an FTIR spectrometer was a flow-through gas cell, known as the light pipe (LP), delivering vapor-phase IR spectra of eluting solutes. Two other cryogenic devices which allowed mobile-phase elimination by trapping the compounds eluting from the GC at sub-ambient temperature have been developed: the matrix isolation (MI) interface operating at 11 K and the direct deposition (DD) window operating at 77 K. Each of these three types of interface has advantages and drawbacks that are discussed in terms of sensitivity and specificity. Some selected applications in selected domains of analytical chemistry, i.e. environment, flavor and fragrances, pheromones and fatty acids, are presented and discussed again in terms of sensitivity and specificity according to the interface type used. Finally some concluding remarks on technique developments for GC/FTIRS and related techniques combining chromatography with IR spectroscopy are given.

1 INTRODUCTION

Structural analysis of individual components in a complex mixture requires the coupling of separative techniques to identification techniques, mainly spectroscopic. For volatile samples capillary GC allows the separation of most samples with high resolution, thanks to the many stationary phases commercially available. For many years, the only coupled technique available for volatile samples was GC/MS. It is one of the most widely used tools for structure determination and many areas of analytical chemistry rely upon capillary GC/MS for both qualitative and quantitative analyses. The determination of the structure of a compound from its mass spectrum can be made in several ways, the initial approach generally consisting in comparison of the experimental spectrum with existing library spectra. When the spectrum is not in any library, complete interpretation of the spectrum, sometimes helped with chemical ionization now available even on very basic benchtop instruments, is more time-consuming, and not always successful. Moreover, MS alone does not solve all the structural problems. Particularly, MS is not able to differentiate some isomers. Generations of chemists have used IR spectroscopy as a powerful tool in the analysis of molecular structures. The informative content of an IR spectrum is very high, with clear identification of chemical functions and substructures. Each molecule possesses its own characteristic IR fingerprint, and the possibility

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

of identifying compounds with very high accuracy by simple examination and matching of their IR spectra has been realized. Moreover, IR is particularly suited to differentiate conformational and structural isomers. Coupling GC with conventional grating IR instruments, when a spectrum takes some minutes to be acquired, was not practically feasible, despite trials essentially in the effluent stopped-flow mode.[1,2]

Taking into consideration the numerous advantages of FTIRS over conventional dispersive IR spectroscopy, among which is the speed of analysis, the first attempts to interface a gas chromatograph to an FTIR spectrometer were made in the late 1960s,[1] even though at that time, the instruments were sometimes used in the stopped-flow mode using high-capacity GC columns,[1,3] and not with on-line detection in the on-flow mode.

Since then, FTIR instrumentation has evolved considerably and compulsory computers provided extreme on-line computing power for less and less cost. State-of-the-art FTIR spectrometers are able to interface with capillary GC and to acquire IR data fast enough to accommodate the narrowest peaks obtained with high-resolution capillary GC. GC/FTIRS appears as a complementary tool to GC/MS for volatile compound identification purpose, but still represents a challenge in terms of sensitivity limits compared to this last ubiquitous technique.

Optimization of GC/FTIRS as a combined technique requires careful attention to all the component parts: GC, transfer lines to the measuring interface, the interface itself, and the IR spectrometer. Each part will be addressed in the following, but not at the same level. Only those parts specific to the technique will be developed.

HRGC using narrow-bore fused-silica wall-coated capillary columns is now standard in most analytical laboratories. Availability of stationary phases as well as capillary column dimensions adapted to a wide range of application, has made the technique widespread. Only specific comments related to the coupling to IR spectrometry will be presented.

It is beyond the scope of this article to present the basic principles of FTIRS. These principles may be found in another article, and in dedicated treatises.[4,5] Only those advantages of FTIRS over conventional grating IR spectroscopy which are relevant to the interfacing of GC will be developed.

The operating principles of GC/FTIRS coupling will be presented, with special emphasis on IR reconstructed chromatograms, IR spectra computation and the spectral library search. Finally, the main part will be devoted to the GC/IR interface. Three types are now commercially available: LP; MI; and DD. Each type has specific advantages and drawbacks, with clear impact on the technique sensitivity.

Some applications in various fields of analytical chemistry will be finally presented in order to illustrate the various interesting possibilities of the method.

2 THEORY AND OPERATING PRINCIPLES

2.1 Fourier Transform Infrared Spectrometry

An FTIR instrument used for coupling to GC is basically a single-beam FTIR spectrometer where the modulated IR beam is delivered by a rapid-scanning two-beam interferometer generally based on the original Michelson design.[4] The Michelson interferometer is a device that can divide a beam of IR radiation into two paths using a beam-splitter and then recombine the two beams within a single modulated beam after a path difference has been introduced by a moving mirror (Figure 1). The interference pattern thus generated by the interferometer, the interferogram, reflects the intensity variations of the beam and can be measured as a function of path difference by an IR detector. This interferogram is the cosine Fourier transform of the spectrum of the incident radiation. As the Fourier transform is mathematically reciprocal, the IR spectrum is calculated by computing the cosine Fourier transform of the interferogram.

All rapid-scanning interferometers usually operate by signal-averaging successive scans. For precise signal-averaging, each interferogram must be sampled at exactly the same retardation delay for every scan. Therefore, very precise matching of the movable mirror is required to control the change in optical path difference. This control is obtained by the use of the interference pattern of the monochromatic light of a He–Ne laser. The sine interference pattern of the laser source, obtained either with the main interferometer or with a dedicated

Figure 1 Schematic representation of a Michelson interferometer.

synchronized separate reference interferometer, allows precise digitization of the IR interferogram at the zero crossings of the laser sinusoidal interferogram. Moreover, with this He–Ne laser, FTIR spectrometers have a built-in wavenumber calibration of very high precision (ca. 0.01 cm^{-1}). This is an important advantage of FTIR instruments over grating spectrophotometers known as the Connes advantage.

Other advantages with clear impacts on coupling with GC are specific to FTIRS. With FTIRS, all the spectral elements emanating from the IR source and transmitted through the sample are simultaneously received at the detector. Contrarily, with grating spectrometers where a monochromator is used, the spectral frequencies reach the detector successively. This multiplex or Felgett advantage allows a better signal-to-noise (S/N) ratio to be achieved, only proportional, at a given spectral resolution, to the square root of the measurement time, and independent of the number of measured spectral elements. The throughput or Jacquinot advantage concerns the energy range of the transmitted IR beam, which is not limited in FTIRS by the linear slits used in grating instruments to reach the desired spectral resolution. This advantage is clearly important when GC/IR interfaces may drastically attenuate the radiation throughput.

Finally, one of the main advantages of FTIR spectrometers in coupling with GC is their rapid-scanning capacity. This allows acquisition of full spectra in fractions of a second, which is mandatory for capillary GC when the duration of a GC peak is typically a few seconds. Using signal-averaging, the sensitivity is also increased as the S/N ratio, dependent on the square root of the measurement time, increases with the square root of the number of scans being signal-averaged.

The last advantage often previously cited[6] for FTIR instruments was the presence of a computer, compulsory for Fourier transform operations. Nowadays, with the availability of compact and inexpensive microcomputers in every analytical laboratory, this advantage can hardly be considered as specific to FTIR instrumentation.

Most of the commercially available GC interfaces are specific accessories to conventional FTIR spectrometers (Figure 2). The collimated modulated IR beam from the interferometer, normally focused at the sample point in the sample compartment, is simply directed by a removable mirror to an external port where the GC interface is connected. The only exception is the IR detector initially commercialized by Hewlett Packard as the IRD™, which is a dedicated GC/FTIR instrument with optimized optics using a vapor-phase LP interface.

2.2 Gas Chromatography Requirements

The separation of volatile components of a complex mixture by GC is widely used by analytical chemists in various fields for both qualitative and quantitative purposes.

Figure 2 A typical FTIR spectrometer used to generate a modulated IR beam.

GC is basically a dynamic technique in which the individual components, the eluates, elute in a few seconds from the column. The dynamic range of component concentration within the sample is generally very high, the components ranging from a few tens of micrograms to a few nanograms or less. Rapid-scanning interferometers capable of acquiring a few spectra within a single second with signal averaging may accommodate the high resolution obtained with capillary GC using conventional wall-coated open tubular (WCOT) columns (0.25 or 0.32 mm internal diameter). Hence, collection of IR spectra of samples in submicrogram quantities is possible, subject to the use of an interface adapted to vapor-phase IR spectra recording.

However, since the IR response is directly related to the concentration of the sample within the GC peak, and to the presence of strong IR-absorbing chemical functions in the molecules, the best S/N ratios will be obtained for strong absorbers focused within a narrow GC peak. Optimization of the GC separation is therefore all the more necessary since the dynamic range of compound concentration within the analyzed mixture is generally very high. This implies that for any GC/IR interface using either on-the-fly detection or eluate trapping very low dead volumes must be used in order to be compatible with HRGC and to avoid peak broadening or even eluates re-mixing.

Finally, the GC column to be used in GC/FTIR applications has to be chosen in terms of sample capacity and achievable resolution.[5] For standard applications with commercial interfaces, conventional WCOT columns of 0.25 or 0.32 mm internal diameter with thin film

thickness are adequate. Chemically bonded and cross-linked stationary phases are advisable to avoid bleeding which may pollute the interface. The dynamic range of compound concentration for GC/FTIRS analysis is determined by column capacity at the upper end and by IR S/N ratio at the lower end.[7]

2.3 Gas Chromatography/Fourier Transform Infrared Spectrometry Coupling

The potential of an FTIR spectrometer interfaced to a GC was realized soon after rapid-scanning interferometers were marketed.[6] It was clear that one application for which the advantages of FTIRS should be beneficial was the on-line measurement of IR spectra of eluates from a gas chromatograph. Since then, the layout of instruments has not really changed (Figure 3), even though the cost for any individual part of this technique has dramatically dropped (this is particularly true for computers) and in the meantime their performances have been considerably improved. The GC/FTIR interface ''box'' will be developed later.

Passing from collected interferograms during a GC run to IR spectra of each individual GC peak requires the steps shown in Figure 4. The first step is to transform the set of collected interferograms into a reconstructed IR chromatogram. To save space on storing media, it is advisable to store only those interferograms which contain relevant spectral information. However, modern storage media may accommodate complete runs.

Basically, and theoretically, to locate the interferograms corresponding effectively to spectra of GC eluates, it is necessary to transform all the collected interferograms of the GC run into their respective spectra and then discriminate solute spectra from background. Clearly this is not of practical use for complex mixtures of several dozen peaks. Alternatively, as the presence of any IR-active

Figure 3 Schematic layout of a GC/FTIR system with the essential parts: interferometer, interface, gas chromatograph, and computer.

chemical in the IR beam should reduce the interferogram intensity, one method consists of calculating the overall absorption power of each interferogram. In this method, analogous to the total ion current (TIC) in GC/MS, however, no reliable results are obtained, because most GC/IR absorbances are well below the practical interferogram intensity difference threshold.[8] Several methods to construct or reconstruct chromatograms from interferometric data have been used to overcome these drawbacks, and some of them have been compared in terms of optimal S/N ratio and computation time.[9] Among the many reconstruction methods proposed so far, two of the early described methods that construct chromatograms directly from the interferometric data are currently used.

The first of the two methods relies on the fast Fourier transform (FFT) algorithm. A spectrum is computed in real time and ratioed against a stored reference spectrum acquired before the GC run and computed at the same resolution. The integrated IR absorbance is calculated in discrete spectral regions, generally corresponding to characteristic absorptions of selected functional groups, to produce spectral window chromatograms. In the original work[6,10] for evident computational limitations, five spectral windows could be defined using $32\,cm^{-1}$ resolution spectra computed in real time from 512 data points around the centerburst of the interferograms collected as single scans at a resolution of $8\,cm^{-1}$. With modern computers it is possible to produce several separate spectral regions or ''windows'' chromatograms calculated from spectra signal-averaged and computed in real time at the spectral resolution used to acquire the interferograms. These functional group chromatograms, that can be compared to single-ion monitoring (SIM) in GC/MS, are useful for identifying GC fractions belonging to a particular chemical class in complex mixtures. The S/N ratio of the functional group chromatograms may be optimized in a straightforward manner if the spectral window is defined precisely around the maxima of the absorption bands to be monitored. This is not always feasible when handling unknown samples, where it is not possible to know the most characteristic wavenumbers in advance.[5] To find suitable spectral ranges for reconstructing window chromatograms, an elegant approach was developed that used spectral data representation as a contour plot.[5,11] In this representation, a routine technique in two-dimensional nuclear magnetic resonance (NMR) spectrometry, the complete spectral information is plotted as contours of absorbance bands in a two-dimensional map of wavenumbers against time coordinates. Using this kind of data representation, even spectral information of overlapping peaks may be used to reconstruct very precise functional group chromatograms.[5,11] The total absorbance across

Figure 4 Procedure used to generate a GC/FTIR transmittance or absorbance spectrum: (a) interferogram; (b) reconstructed IR chromatogram; (c) single-beam reference spectrum measured when no GC peak is eluting; (d) single-beam sample spectrum of eluting compound; (e) transmittance spectrum, ratio of (d/c); (f) absorbance spectrum.

the entire spectral region can be calculated to give a reconstructed chromatogram independent of the window regions that have to be chosen by the operator and where all the peaks may be observed, but at the cost of the S/N ratio.[6]

The other method that may be used for real-time reconstruction of chromatograms directly from interferometric data is the Gram–Schmidt (GS) vector orthogonalization method developed by de Haseth and Isenhour.[8] The GS method does not involve any Fourier transform as it relies on the multiplex nature of the interferogram: a single interferogram contains complete spectral information on absorbing samples. Therefore, a portion of the interferogram contains sufficient information to determine whether an eluate is present in the IR beam or not. In this technique, a reference set of x interferograms is collected immediately before the GC run. A small segment of each reference interferogram near the centerburst is selected. Consecutive values of the interferogram portion are treated as a vector. If n data points are chosen, they are treated as an n-dimensional vector $\mathbf{I}$ in hyperspace as shown in Equation (1).

$$\mathbf{I} = (i_1, i_2, i_3, \ldots, i_n) \tag{1}$$

where $i_1, i_2, i_3, \ldots, i_n$ are the n consecutive values of the interferogram portion, or the coordinates of the vector in the hyperspace. Using the set of x reference interferograms, a set of x orthogonal basis vectors is constructed. This set of basis vectors forms a multidimensional reference hyperspace and represents the background conditions, i.e. the optics characteristics when no sample eluting from the GC column is present in the light path. Each single-scan interferogram in a subsequent GC/IR run is treated in the same way as a sample vector. This sample vector can be orthogonalized and compared to the existing basis, and the absolute length of the resulting scalar from each interferogram measures the total IR absorbance of any IR active sample in the IR beam,[8] i.e. refers to the quantity of eluate in the light path. To a certain extent, GS reconstructed chromatograms can be compared to TIC chromatograms in GC/MS, since each absorption band contributes to the signal. However, this must be relativized, as the signal is also dependent on the molar absorptivities of bands which tend to be much greater in the IR spectra of polar molecules than in those of nonpolar molecules.[6] Optimization of GS parameters (offset from the centerburst of the interferogram, number of interferogram data points used to build the vectors, number of basis vectors in the reference hyperspace) has been the subject of specific work.[5] A good compromise seems to deliver an optimum signal giving acceptable S/N ratio for the reconstructed chromatogram when 100–150 consecutive data points are selected from the interferogram in the region starting ca. 30–50 data points from the centerburst, and when approximately 10 reference vectors are included in the basis set.[4,5] The algorithm being very rapid, GS reconstruction can be done in real time simultaneously with data collection with uncompared sensitivity. It has also been demonstrated that GS chromatograms, the magnitude of which being dependent on the absorptance (1 minus transmittance) of the absorbing material, may be used for quantitative studies, as at the low concentrations typically used for GC/FTIR, absorptance varies linearly with compound concentration.[5,7]

Despite some tentative chromatogram reconstructions with digitally filtered interferograms, leading to the selectivity of the FFT method at the computational speed of the GS method,[12] and with claimed advantages on combined selectivity, S/N ratio and computational speed, the GS method remains the standard method to reconstruct total IR chromatograms. Once a reconstructed IR chromatogram has been computed from interferometric data using any reconstruction method, it is necessary to produce an interpretable IR spectrum for each peak in the mixture. This is generally done as illustrated in Figure 4. A single-beam background spectrum showing characteristics of optics, interface and detector is calculated from a region of the chromatogram where no compound is eluting, preferably not too far from a peak of interest. A single-beam sample spectrum is obtained from the interferometric data corresponding to an eluate, generally by co-adding several interferograms within the chromatographic peak, before applying FFT. Each saved interferogram is the result of the co-addition of a few (four to five) single interferograms, for signal-averaging and S/N ratio purposes.

The final transmittance or absorbance (−log transmittance) spectrum is calculated by ratioing the single-beam spectra. If the database spectral search is to be carried out on experimental spectra, the data must be expressed as absorbance spectra.

2.3.1 Spectral Resolution

The spectral resolution in FTIRS depends on retardation, or optical pathlength difference. Namely, to resolve two spectral lines separated by a distance $\Delta\nu\,\mathrm{cm}^{-1}$, the retardation $\delta\,\mathrm{cm}$ should at least be $\delta = (\Delta\nu)^{-1}$, and if the maximum retardation of an interferometer is $\Delta\,\mathrm{max}$, the best spectral resolution achievable with this interferometer is $\Delta\nu = (\Delta\,\mathrm{max})^{-1}$. Increasing the resolution, i.e. increasing the retardation, results in increasing measurement time. Clearly, in GC/FTIR coupling, the measurement time cannot be extended too much and the optimum one is determined by the elution duration of a GC peak for on-the-fly detection, taking into account signal-averaging constraints. To improve the precision of band maximum determination and photometric accuracy, interpolated points may be added in the spectrum by extending the interferogram data points with zeros before computing. This zero filling procedure (one level of zero filling doubles the file size for Fourier transformation) increases the digital resolution of the spectrum without introducing any error itself, as the raw data and the instrumental line shape are not affected. For most of the GC/IR analytical problems, a spectral resolution of $8\,\mathrm{cm}^{-1}$ and one level of zero filling before FFT seem an acceptable working compromise.[5] For specific needs, a higher spectral resolution may be used (i.e. $4\,\mathrm{cm}^{-1}$) but at the cost of decreased S/N ratio when the measurement time cannot be increased.[5]

3 THE GAS CHROMATOGRAPHY/FOURIER TRANSFORM INFRARED INTERFACES

An important breakthrough for FTIRS, which partly explains the rapid developments of GC/FTIR coupling, was the introduction of the narrow-range mercury cadmium telluride (MCT) photodetector cooled to liquid

nitrogen temperature. The specific detectivity of this detector is more than an order of magnitude greater than that of the standard deuterated triglycine sulfate (DTGS) pyroelectric bolometer supplied with most commercial FTIR spectrometers. Moreover, the MCT photodetector accommodates the high modulation frequencies necessary for GC/FTIRS, when the DTGS response decreases with increasing interferogram modulation frequency.[4,5] The first demonstration of GC/FTIRS was effective soon after the commercial achievement of rapid-scanning interferometers. Thus Low and Freeman[13] reported on-the-fly IR detection of GC eluates from a packed column using a small flow-through gas cell (ca. 0.6 mL volume) placed between the source and the interferometer.[13] Soon after, the first GC/FTIR accessory, consisting of a gas cell that fitted inside the spectrometer sample compartment, collected interferograms for packed column chromatography using either flow-through or trapped (stop-flow) modes.[4] In 1974 Azarraga and McCall (cited by Griffiths and de Haseth[4]) showed that capillary GC/FTIRS could be performed using a support-coated open tubular column with on-the-fly sampling using the gas cell (or LP) GC/IR accessory. A major breakthrough was the development of gold-coated borosilicate glass LPs by Azarraga.[14] These LPs were constructed to have a very high transmittance and they allowed the coupling of WCOT columns.[15] Today, most FTIR vendors propose optimized LP accessories for GC/FTIR coupling to fused-silica WCOT GC columns.

3.1 The Light Pipe

A typical arrangement for a GC/FTIR system using a LP interface is represented schematically in Figure 5. Clearly, the interface has to be optimized from both chromatographic and spectrometric points of view. In a typical GC/IR measurement the effluent from the GC column is passed through a heated transfer line continuously to a heated measuring gas cell, the LP. Meanwhile, the modulated IR beam collimated through an external port of the interferometer is focused to an IR-transparent window at the entrance of the LP. The radiation containing information of absorbing material within the effluent exiting from the LP is focused onto the MCT detector element. The effluent getting out of the LP may be directed, through another heated transfer line, to a conventional GC detector, as IR detection is nondestructive.

Figure 5 A typical GC/FTIR LP interface arrangement.

The LP (Figure 6) is essentially a gold-coated glass tube. The gold coating allows the IR beam to undergo multiple reflections in order to enhance the overall optical throughput of the cell. This material is assumed to be chemically inert, remarkably resistant and stable, an important advantage for a material that must be necessarily heated and that should be chromatographically inert. The high temperature of the LP is however a problem as a large decrease in signal intensity occurs

Figure 6 Schematic LP interface.

with increasing temperature. This effect results from high levels of unmodulated IR radiation emitted from the hot LP, this being an IR radiator itself, radiation which saturates the detector or its associated preamplifier.[16] Using a cold shield positioned at the end of the LP eliminates the emission from the hot LP.[16] However, it was then demonstrated that the same improvement may be obtained by using a simple optimized optical configuration where the IR beam exiting the LP is precisely focused on the detector element.[17] Practically, the temperature of the LP will be normally dictated by the upper temperature used in the GC analysis.[5]

From the GC point of view, the LP and transfer lines are dead volumes, especially when using narrow-bore GC columns. Generally, the column or fused-silica tubings are fed through the heated transfer lines up to the entrance and the exit of the LP in order to have a virtually zero dead volume. The size and geometry of the LP have been the subject of theoretical studies.[4] Clearly the length, inner diameter and length-to-diameter ratio are critical factors in achieving good S/N ratios in the resulting spectra. Ideally, the volume of the LP, V_{cell}, should not exceed the volume of carrier gas between the half-height points, $V_{1/2}$, of the narrowest peak in the chromatogram[4,6,18] to avoid a severe degradation of the GC resolution. Obviously this requirement cannot be fulfilled in every circumstance, and the practical LP volume should be a compromise between optical throughput and chromatographic considerations. A reasonable choice will depend on the most frequently used column type.[5] For narrow-bore fused-silica columns cell volumes between 50 and 150 μL are typical, and adding make-up gas could be advantageous when the volume of the LP exceeds the volume of the GC peaks. A comprehensive review of the hardware from transfer lines to optics, including sampling considerations, may be found in a specialized treatise.[4] Some practical information may be found in a monograph by Herres.[5] The sensitivity of the LP interface in terms of detection limits is in the nanogram range. Even though some studies report detection limits at the subnanogram level, it should be assumed that it was achieved only for exceptionally strong absorbing analytes. Moreover, as already outlined in 1984 by Cooper and Taylor,[19] published detection limits do not reflect the amount of material required for a positive identification, especially when spectral search identification is being used. The ''practical'' limit of detection/identification is in the tens of nanograms range for compounds that are good IR absorbers and fairly volatile. This limit is clearly higher for poor absorbers and less volatile compounds. This limit seems the threshold limit obtainable with an LP system, even with carefully optimized optics,[17] as no significant improvement has been made since the development of LP interfaces adapted to narrow-bore fused-silica WCOT GC columns.[7,20–22] A typical vapor-phase IR spectrum is presented in Figure 7. This spectrum was obtained with ca. 1 μg of 3-hydroxy-5-methyl-2-hexanone after on-column injection of an aromatic extract of water buffalo milk.[23] On-the-fly IR detection of eluates from GC separation within the LP makes this technique a true real-time system.

Figure 7 Vapor-phase IR spectrum of 3-hydroxy-5-methyl-2-hexanone.

3.2 The Matrix Isolation Technique

As outlined above, even an optimized LP system is not sensitive enough to solve all the problems amenable to HRGC and HRGC/MS. One possible way to gain substantial sensitivity, that is to enhance the S/N ratio, is to raise the sample absorbance and to lengthen the observation time per sample. This could be achieved by means of cold trapping the components using a suitable trap capable of freezing out highly volatile compounds, followed by off-line IR measurement with extensive signal-averaging if necessary. This can be done by using a technique known as MI.

The MI technique has been extensively used to study detailed spectrometric properties of a large variety of molecules, free radicals and ions.[4] In this technique, the molecules under investigation are co-condensed on a spectroscopically transparent window or an IR-reflecting surface with a large excess of an inert and IR-transparent gas, such as argon, at cryogenic temperatures (below 20 K) under vacuum. Trapped and diluted in a solid matrix at these temperatures, the individual molecules do not interact with each other and the molecular rotational motion is absent. As a consequence, IR absorption bands sharpen significantly, and even small shifts and band splitting may occur.

Early work demonstrated the feasibility of coupling GC to MI/FTIR,[24–26] although these original interfaces suffered from the same problem of insufficient focusing of the GC eluate on the cryogenic surface, precluding any significant gain in sensitivity. An optimized version

Figure 8 Original layout of the GC/MI/FTIR interface. (Reproduced by permission of the American Chemical Society from Reedy et al.[27])

Figure 9 Enlarged view of the sample collection surface and deposition tip of the MI interface. (Reproduced by permission of the American Chemical Society from Reedy et al.[27])

was described in 1985[27] with claimed sensitivity in the 100 pg range, giving rise to a commercial GC/MI/FTIR instrument, known as the Cryolect™, the interface being developed by the Cryolect™ Scientific Corp., and available at that time from Mattson Instruments. In this system, presented schematically in Figure 8, the cryogenic surface was the gold-plated mirrored surface of a rotating cryogenic disk or ''cryodisk''. The cryodisk was placed in a vacuum chamber and maintained at a temperature of 11 K by a closed cycle helium refrigerator which did not require the use of liquid helium. The sample inlet port and the IR beam port were found on opposite sides, facing the curved surface of the cryodisk. The sample inlet port was a capillary tube passing through a copper block and a metal nozzle sealed into a Pyrex window. The end of the capillary tube protruded slightly from the nozzle. The Pyrex window and attached binocular microscope allowed observation of the nozzle and capillary tip, so that the position of the latter could be precisely adjusted with respect to the surface of the cryodisk. For IR data collection, a pair of off-axis paraboloid mirrors (M2 and M4 in Figure 8) were mounted outside the vacuum chamber. The first one focused a collimated IR beam coming from a FTIR spectrometer onto the mirrored surface (M3) of the cryodisk through a thin fused KCl window. In reflecting from the mirrored surface M3, the IR beam passed twice through condensed material and was redirected and collimated by mirror M4 towards a MCT IR detector. Figure 9 displays an enlarged view of the sample collection surface. Fused-silica capillary tubing, 150 μm in diameter and separated by 150 μm from the collection surface, protruding slightly beyond the heated nozzle, directed the GC effluent against the mirrored surface of the cryodisk. The helium carrier gas, noncondensable at the working temperature and eliminated in vacuo, was balanced with 2% argon. The argon and sample molecules formed a solid layer on the cold surface. The eluates from the chromatograph were retained in sequence in the track of frozen argon on the surface of the rotating cryodisk. Each collected compound was contained within an area typically 0.3 mm in diameter yielding a high level of spectral absorbance per mass unit of sample. Measurement of IR spectra by specular reflectance from the metallic surface was made by rotating the cryodisk after deposition was completed so that the portion of the solid argon matrix that contained components of interest was placed at the focus of the IR beam. Computer-controlled disk motion facilitated this operation, as did retention time data obtained with the flame ionization detector (FID) of the GC by dividing the

GC effluent in two parts, but GC/MI/FTIRS using this interface could not be considered as a real-time technique, as post-GC run operation was necessary. However, once a compound was deposited, extensive signal-averaging could be done if necessary to enhance the S/N ratio of spectra obtained for diluted samples or poorly absorbing molecules. The deposited compounds were removed from the cryogenic sample collector by warming it up after completion of the data collection.

These results demonstrated the achievement of MI of molecules eluting from a high-resolution gas chromatograph without any loss of separation power.[27] The gain in sensitivity was estimated to attain a factor between 10 and 100 compared with LP GC/FTIRS.[20] The GC/MI/FTIR sensitivity was found to be quite similar to the current GC/MS sensitivity (i.e. low nanogram range). Both detection modes were implemented in parallel on some Mattson-Cryolect™ commercial instruments by dividing the effluent from the GC into two parts. This rendered the instrument highly efficient with two compatible and highly complementary identification techniques. Figure 10 shows an example of MI spectra obtained in the original work with ca. 60 ng of dioxin samples.

Figure 10 GC/MI/FTIR spectra for ca. 60 ng of *p*-dibenzodioxin and 2,3,7,8-tetrachloro-*p*-dibenzodioxin. (Reproduced by permission of the American Chemical Society from Reedy et al.[27])

Specificity of MI IR spectra, particularly sharp absorption bands, is due to the absence of band broadening following molecular rotation or intermolecular interaction. These spectra can be considered as pure IR vibrational spectra. This specificity allows straightforward discrimination among closely related isomers, discrimination simply impossible to achieve with the LP interface, or even with traditional IR spectra obtained in the condensed phase.[20,27]

The major disadvantages of the GC/MI/FTIR technique are its complexity, the hardware being more sophisticated and requiring more precise construction than the LP interface, and its higher cost. Moreover, the MI interface requires intensive training to maintain and operate, particularly for the optical bench alignment procedures.[28] Another drawback is that argon matrix spectra are different from the conventional spectra obtained in condensed phase and also different from gas-phase spectra. Moreover no commercial library is available with spectra acquired under these conditions. However, spectral specificity with subsequent unparalleled identification power, sensitivity enhancements due to the concentration of the analyte, extensive signal averaging and peak sharpening, and complete compatibility with demanding high-resolution capillary GC are unique features of the MI interface. Unfortunately, for some years the Mattson-Cryolect™ instrument has not been commercially available. A new instrument (vide infra) is available in the US, the MI-TREK™ commercialized by Reedy Scientific Instruments (Bourbonnais, IL).

A major drawback of MI technology is that it operates at the very low temperature of 12 K. Efforts have been made in order to increase the working temperature to the liquid nitrogen temperature using matrixless deposition of eluates at 77 K or MI in xenon at 65 K.[29] Subambient temperatures (−10 to −45 °C) have also been investigated using eluate trapping on an IR-transparent window moved to the focal plane of an FTIR microscope which allowed IR data collection shortly after the eluate was deposited.[30,31] By placing the IR-transparent window in a vacuum chamber and adapting the optics, it was possible to obtain IR transmission spectra of eluates trapped at the liquid nitrogen temperature (77 K) in ''pseudo real time'' with subnanogram sensitivity.[32] This work was the basis for the development of a commercial real-time DD interface for GC/FTIRS.

3.3 The Direct Deposition Interface

Performance characteristics of the DD interface commercialized by Bio-Rad Laboratories as the Tracer™ GC/IR interface were described by Bourne et al.[33] in 1990. A schematic of the optics, sample collection device and

Figure 11 Layout of the commercial DD GC/FTIR interface (Tracer™) with eluate deposition scheme. (Reproduced by permission of Bio-Rad SA.)

the layout of the commercial instrument is presented in Figure 11. The sample slide, mounted on a copper cold-block, is a rectangular ZnSe window transparent to the IR. This assembly is mounted on a motorized XY stage inside a vacuum chamber maintained at 10^{-5} Torr by a turbomolecular pump. The ZnSe window is cooled with flexible thermal transfer lines placed between the moving cold-block and a liquid nitrogen reservoir (Figure 11). With this arrangement the temperature of the window never exceeds 97 K.[33] The heated transfer line from the GC incorporates an orifice of 50 μm internal diameter positioned 50 μm from the surface of the window, close to the focus point of the IR beam. The analytes in the effluent are deposited on the window as small frozen spots of approximately 100 μm width. The window is moved continuously step by step, and each spot passes through the IR beam just after a short time delay, making the technique a "quasi" real-time one (Figure 11). The IR beam is transmitted through the sample and window, and collected for transmission to an MCT detector by a Schwartzchild microscope attachment. As the position and movement of the ZnSe window are under computer

Figure 12 GC/DD/FTIR real-time spectrum of ca. 50 ng of 2-hexanone present in a complex mixture of volatile compounds.

control, the window may be repositioned for post-run IR measurements with extended signal-averaging for improved S/N ratios, as they are with the MI system. The IR spectra are obtained in the condensed (solid) phase, in the traditional transmittance mode. An example is presented in Figure 12. It has been demonstrated that DD spectra may be directly searched against conventional libraries of IR spectra of reference materials prepared as KBr disks.[33,34] Low subnanogram sensitivity down to a few tens of picograms has been demonstrated with this GC/DD/FTIR interface for a variety of chemicals with real-time measurement.[33,34]

3.4 Gas Chromatography/Fourier Transform Infrared Spectra and Sensitivity

The three different GC/IR interfaces based on three different principles lead to different IR spectra. The heated LP interface, the MI cryogenic system and the DD device give gas-phase, matrix-isolated and solid-phase spectra, respectively. This implies that the different spectra acquired in the different modes are significantly different in terms of absorption band intensity and width, and in terms of band position. A shift to higher frequencies

Figure 13 GC/FTIR spectra of methyl elaidate obtained in the vapor phase with an LP interface (a) and in the solid with a DD interface (b).

is noticed on changing from solid to liquid to gaseous state. This change is accompanied by a general narrowing and an intensity decrease for the bands involved in hydrogen bonding in the condensed phase. Gas-phase spectra give broad absorption bands due to enhanced rotational motion in the heated LP. For important characteristic bands that could be weak, this is particularly a handicap. On the other hand, solid-phase spectra obtained with the DD interface give rise to sharper and more intense bands. For comparison purposes, Figure 13 shows the IR spectra of a $C_{18:1}$ unsaturated fatty acid methyl ester possessing a *trans* double bond, methyl elaidate. The position of the main absorption bands (C−H stretching and carbonyl stretching) are different, shifted towards lower frequencies by ca. 10 cm^{-1} for C−H stretching from 2933 in the gas phase to 2923 cm^{-1} in the solid and 20 cm^{-1} for the C=O stretching from 1759 in the vapor phase to 1739 cm^{-1} in the solid state. The respective ratios between these bands are also clearly different. On the contrary, the C−H out-of-plane deformation band, characteristic of the trans double bond, is found at the same wavenumber (968–969 cm^{-1}) for both modes but with a clear advantage for the solid-state spectrum from the intensity standpoint. (This characteristic band which appears invariant is found at the same position around 970 cm^{-1} in MI spectra.[35])

MI spectra are different from both gas-phase and solid-state spectra. As already outlined, they are pure vibrational spectra, resulting with sharp absorption bands. Practically, as it is shown in Figure 14, they can be considered as intermediates between gas-phase spectra (in terms of band position) and solid-phase spectra (in terms of band intensity). For instance, the matrix isolated spectrum of a conjugated *trans,trans*-$C_{18:2}$ diunsaturated fatty acid methyl ester displays C−H and carbonyl stretchings at 2935 and 1754 cm^{-1}, respectively, close to the corresponding gas-phase features, but the respective intensities are those of the solid-state spectrum (Figure 14b) in which however the bands are found at lower frequencies (2923 and 1739 cm^{-1} respectively). On the other hand, the C−H out-of-plane deformation band, characteristic of the conjugated *trans,trans* configuration, is found at exactly the same frequency (990 cm^{-1}) with comparable relative intensities.

Another structural feature worth mentioning here is the hydroxyl stretching vibration of alcohols. As in the solid phase obtained with the DD interface intermolecular forces such as hydrogen bonding are present, the OH stretching bands are significantly broadened, as they are with KBr disks or neat films. Therefore the OH stretching band appears as a very broad band between 3500 and 3000 cm^{-1} (Figure 15). MI spectra of alcohols display intense and sharp absorption bands for the OH

Figure 14 GC/FTIR spectra of a conjugated *E*,*E*-C18 : 2 methyl ester obtained in an argon matrix with an MI interface (a) and in the solid state with a DD interface (b). (Spectrum (a) reproduced by permission of Preston Publications from Mossoba et al.[82])

stretching, resulting from the collection of the separated compounds under MI conditions, that are highly structurally informative.[24] Vapor-phase spectra of alcohols display weak bands for the OH stretching (Figure 7 and Figure 15) revealing the lack of intermolecular interaction, but their positions are also highly structurally informative (i.e. it is easily possible to distinguish between primary, secondary and tertiary alcohols[36]). Moreover, as rotational motion is allowed in the heated interface, intramolecular interactions such as intramolecular hydrogen bonding are allowed, resulting in a significant decrease in the OH absorption frequency, a decrease of high structural significance. Thus, the OH stretching vibration of the compound presented in Figure 15 found at 3611 cm^{-1} could be attributed to a hydroxyl function of a secondary alcohol involved in intramolecular hydrogen bonding (with a carbonyl function revealed by the carbonyl band found at 1738 cm^{-1}) and this observation was of prime importance for the structural characterization of this compound found in a pheromonal secretion of a cockroach and identified as 3-hydroxyhexanal.[37] Another example of the importance of such an observation, a unique feature of gas-phase IR spectra of alcohols, will be presented below (see section 4.3).

As already outlined, only the cryogenic interfaces such as the MI or DD devices possess intrinsic sensitivity fully compatible with demanding GC analyses that can be easily handled by GC/MS. This has been fully documented (see Le Quéré and Sémon[22] for example). Very low detection limits (to the picogram range) have been published for both cryogenic interfaces,[28,33] but these limits have been obtained with extensive signal-averaging in post-GC runs, and not on a regular routine basis. Nevertheless the cryogenic interfaces have a detection limit of one or two orders of magnitude lower than that of the LP interface. For the latter, it seems that no significant improvement should be obtained, due to the technique itself.

One of the claimed advantages of the DD interface is that the spectra obtained in the solid state may be searched in conventional IR spectral libraries, where spectra are generally obtained as KBr disks.[33] Spectra obtained by this interface are characteristic of a solid-phase sample in an amorphous state. However some typical crystalline features such as band splitting and fringing effects can be noticed. Significant differences between the two types of spectra could be observed, and some bands, like the carbonyl ones, are shifted at lower frequencies by about 10 cm^{-1} for solid-state spectra obtained at cryogenic temperature.[38] Moreover, water introduced into the system either by the sample or as a result of poor conditioning gives solid ice on the window, which results in band broadening. It appears necessary to dry the chamber under vacuum for 1 day after opening it to the atmosphere for routine maintenance.[38] In their original work, Bourne et al.[33] demonstrated the possibility of searching a vapor-phase library for nonpolar compounds such as chlorinated pesticides when only the fingerprint region is included for the search. However when the analytes contain some moieties that may be involved in intermolecular interactions such as hydrogen bonding, it is advisable to use a database for spectral searching where the reference materials are in a similar state to the unknown analytes.[33]

Vapor-phase reference spectra are available in various libraries such as the Environmental Protection Agency library of vapor-phase IR spectra, the Sadtler–Heyden spectra,[36] the Aldrich library of FTIR spectra[39] and the Sadtler vapor-phase IR database (Bio-Rad Laboratories, Sadtler Division). To our knowledge, no MI reference spectral library is commercially available. Table 1 summarizes a comparison of the characteristics of the three techniques discussed in this paragraph.

Figure 15 GC/FTIR spectra of 3-hydroxyhexanal obtained in the gas phase (a) with an LP and in the solid state (b) with the DD interface. (a) was obtained with ca. 1 µg injected on column. (b) was obtained with 50 ng injected splitless.

Table 1 Characteristics comparison of GC/FTIR interfaces

Characteristic	MI	DD	LP
Limit of detection	pg level	pg level	ng level
Limit of identification	<1 ng	<1 ng	10 to 1000 ng, depending on volatility and polarity
Cost	+++	++	+
Sample processing	Two-step process Post-run signal-averaging	Pseudo real-time technique Post-run signal-averaging	"On-the-fly", true real time No post-run signal-averaging
Specificity	Matrix-isolated spectra Sharp absorption bands	Solid-state spectra	Vapor-phase spectra Broad absorption bands
Spectral search	No commercial libraries	Universal condensed-phase spectra libraries available	Vapor-phase libraries available

4 SOME APPLICATIONS OF GAS CHROMATOGRAPHY/FOURIER TRANSFORM INFRARED SPECTROMETRY

It is beyond the scope of this article to give an exhaustive overview of the applications of GC/FTIR in analytical chemistry. In fact, all the problems amenable to GC may use FTIR as a powerful detector. However in order to illustrate the capabilities of the technique, some selected examples from selected domains will be presented. An early comprehensive review may be found in a specialized treatise[5] and dedicated contributions appear periodically in specialty journals.

4.1 Environmental

Substantial efforts have been made to apply GC/FTIRS for qualitative and quantitative environmental analysis of typical environmental contaminants.[40,41] The claimed advantages were specificity and selectivity, IR being able to distinguish between isomers, and the complementary nature of GC/FTIRS and GC/MS was soon acknowledged.[41] Efforts made to improve the performance of GC/FTIR interfaces, particularly the LP interface, were very often motivated by environmental issues (see Gurka et al.[42] for example). This system finally exhibited minimum identifiable quantities in the 10–50 ng range for standards, soil samples and a herbicide still-bottom.[43] Quantitative capabilities of GC/FTIRS were also clearly demonstrated for priority pollutants.[44]

Cryogenic GC/IR interfaces showed improved sensitivity: minimum identifiable quantities ranged from 0.5 to 2 ng in one study on polynuclear aromatic hydrocarbons and pesticides using the DD interface.[45] As an example Figure 16 shows the GC/FTIR spectrum of 2 ng DDT (dichlorodiphenyltrichloroethane) obtained on-the-fly with this interface. A sensitivity down to 100 pg has been demonstrated with this interface for on-the-fly detection of hexachlorobenzene.[46] A picogram level quantitation of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin in fish extracts has also been reported for the MI interface.[28]

4.2 Flavor and Fragrances

Identification of flavor and fragrance molecules is a major field of application for GC/IR. The complementary nature of GC/IR and GC/MS for the structural analysis of volatile flavor compounds was recognized very early on, with particular emphasis on the unique ability of IR spectroscopy to distinguish individual isomers.[7,21,47,48] The early literature through to the end of 1985 has been covered,[5] with applications to the aroma composition of tropical fruits,[49–51] alcoholic beverages,[52] and the volatiles emanating from intact fruits of *Coffea arabica*.[53] The technique has been demonstrated to be very powerful for the analyses of essential oils, and especially for the structural investigation of terpenes and sesquiterpenes where unequivocal identification by MS alone is very often difficult and when FTIR delivers spectra with clear fingerprints.[11,54–58] Recent investigations used the DD interface for increased specificity and sensitivity, where IR spectra matched the documented literature spectra obtained as liquid or KBr pellets.[59] The usefulness of the MI technique for the analyses of flavor extracts has also been demonstrated.[60]

Figure 16 GC/DD/FTIR spectrum of 2 ng DDT. (Reproduced by permission of the American Chemical Society from Gurka et al.[45])

In flavor research coupled GC/FTIRS in conjunction with GC/MS is now a routine tool for characterizing the structure of the volatile components.[22,61,62] The LP system is very often chosen for its ruggedness and low cost, even though the cryofocusing devices present an intrinsic sensitivity one or two orders of magnitude lower.

4.3 Pheromones

Insect pheromones or plant-emitted substances involved in insect–plant interaction are other volatile components that have benefited from the complementary nature of GC/MS and GC/FTIRS. Recent work in the domain uses the sensitivity advantage of the DD interface (see Ferary et al.[63] for example) and coupling with solid-phase microextraction (SPME) adds some advantages.[38] However, a lot of results have been obtained in the vapor phase with the LP interface.[37,64–67] Figure 17 shows the IR spectrum of a female-specific compound isolated from the tergal gland secretion of a primitive cockroach *Cryptocercus punctulatus*. This primitive woodroach lives in galleries in rotten wood and it is the best living representative of the ancestral blattarian-isopteran stock. Besides, several aspects of its life and morphology

Figure 17 GC/LP/FTIR spectrum of 4,6,8-trimethyl-7,9-undecadien-5-ol from the tergal gland of the primitive cockroach *Cryptocercus punctulatus*. (Reproduced by permission of Plenum Press from Le Quéré et al.[64])

strongly resemble the termites[64] and a better knowledge of its biology is of fundamental interest.

The IR spectrum confirmed the presence of a hydroxyl group in the pheromonal compound, the OH stretching frequency (3668 cm^{-1}) falling in the range of secondary alcohols.[36] Another stretching frequency (3605 cm^{-1}) revealed intramolecular hydrogen bonding, probably resulting from the interaction of one of the carbon–carbon unsaturations present in the molecule, via a $(5 + \pi)$ intramolecular hydrogen-bonded system.[36] This feature, unique to vapor-phase spectra as already outlined, fixes the position of the hydroxyl group relative to the carbon–carbon double bond, and is therefore highly structurally informative. The medium absorption at 960 cm^{-1} was attributed to a CH out-of-plane deformation of a trans disubstituted ethylenic bond. These data greatly helped to propose the structure 4,6,8-trimethyl-7,9(*E*)-undecadien-5-ol for the pheromonal compound.[64] This hypothesis was confirmed later with the synthetic compound.

4.4 Fatty Acids

IR spectroscopy has long been used as a dedicated method to distinguish between cis and trans isomers and to determine the total amount of trans fatty acids in fats and oils. The IR analysis of individual isomers in complex mixtures of unsaturated fatty acids was made possible through the combined GC/FTIR technique. The first example published in the literature described the analysis of unsaturated cyclic fatty acid mixtures isolated from heated oils using an LP interface.[68] This interface type was extensively used to characterize geometrical isomers of polyunsaturated fatty acids (PUFAs) in various applications.[69,70] However, it was soon recognized that greater instrumental sensitivity compatible with HRGC was required to determine the minor components found in mixtures with extremely unbalanced dynamic range of concentration (i.e. levels of minor components such as trans PUFAs less than 1%). In this respect, the MI interface was successfully used by Mossoba et al.[35,71] Examples of characteristic spectra have already been presented above. More recently, it has been demonstrated that the DD interface is also particularly well suited to the study of complex fatty acid mixtures.[72]

5 PERSPECTIVE

GC/FTIRS is a valuable tool for the analytical chemist whose main concern is the structural determination of volatile compounds or any component that can be separated by GC. LP technology has reached a standard of achievement limited in terms of sensitivity and specificity, but still very useful and easy to use and maintain. The cryogenic effluent-trapping techniques, i.e. MI and DD, despite their intrinsic sensitivity are not common instruments in analytical laboratories, probably due to their cost and to their inherent sophistication. The MI Cryolect™-Mattson instrument has not been available for some years, and, to our knowledge, the DD Tracer™ Bio-Rad instrument is no longer commercially available. A new MI system appeared recently, the MI-TREK™ (Reedy Scientific Instruments, Bourbonnais, IL), for which a comprehensive review has been published.[71] Based on the original design (vide supra), the MI-TREK™ has however distinct advantages that will be depicted in the following text.

The interface between the IR spectrometer and the GC is a compact vacuum chamber containing the sample collector and the optics necessary to focus the IR beam on the surface of the collector (Figure 18). The IR beam coming from the interferometer is deflected by a plane mirror to enter the vacuum chamber. Within this vacuum chamber it reflects from a plane mirror towards the first of twin paraboloidal mirrors attached to a single block of aluminum. The two paraboloids have a common focus on the mirrored surface of the collector where the samples are matrix-isolated. The IR beam reflects to the second twin mirror, and then the beam is collimated to the paraboloid mirror at the detector. Contrarily to the original design, the collector disk is in a vertical position (Figure 19). It rotates counter-clockwise during sample collection. This arrangement allows the collection surface where the samples are trapped in a layer of argon matrix to move from the ''sample delivery point'' to the ''IR scan point'' within a short delay, making the technique a ''pseudo real-time'' one like the DD interface. Cooling for the cryogenic surface is provided by a closed-cycle helium refrigeration system which requires no liquid helium.

Figure 18 Layout of the MI MI-TREK™ GC/FTIR system. (Reproduced by permission of Marcel Dekker Inc. from Reedy et al.[71])

The refrigerator provides two stages within the vacuum chamber. The first stage operates at 50 K and provides cooling for a reflector shield (Figure 19) which reflects environmental radiant heat and collects background gases such as H_2O and CO_2. The sample collector itself is supported and cooled by the second stage of the refrigerator operating at 10 K.[71] The MI-TREK™ system has been designed to incorporate parallel MS detection by dividing the GC effluent in two parts, with ca. 25% directed to the MS detector. The intrinsic sensitivity of the cryogenic GC/IR interface makes this double-hyphenated technique useful. In fact, all the cryogenic interfaces operating under vacuum are fully compatible with MS, which also operates under vacuum. However simultaneous detection is only possible by dividing the GC effluent in two parts. Contrarily, as the LP system allows on-the-fly IR detection, it is possible to attach an MS detector at the exit of the LP. But as the MS detector is far more sensitive than the IR one, it is also necessary to split the GC effluent (ca. 1/14) to the MS.[44] Many efforts have been made to develop GC/FTIR/MS systems,[73,74] but this double-hyphenated technique is not widespread despite its potential.

Among the technical developments on the combination of chromatography and FTIR spectrometry, the coupling of high-performance liquid chromatography (HPLC) and supercritical fluid chromatography (SFC) to a FTIR spectrometer has received considerable attention. Specific problems related to mobile phases used in HPLC arose with HPLC/FTIRS: no solvent used within the mobile phases is transparent to IR radiation. The use of a flow cell interface necessitates a limitation of the pathlength, resulting in a significant limitation on the sensitivity. Several approaches to eliminate the solvent prior to the IR measurement have been described[31] and subnanogram detection limits have been reported even for reversed-phase HPLC/FTIR using a DD interface.[75] Like GC/FTIRS and HPLC/FTIRS, both flow cell and mobile-phase elimination devices have been described for SFC/FTIRS. Despite the fact that flow cell must accommodate very high pressures,[76] many results have been obtained with this technology, essentially because the transmittance of supercritical CO_2, the most popular fluid used for SFC, is significantly greater than that of most HPLC mobile phases.[31] The method was successfully applied in various fields such

Figure 19 Enlarged view of the sample deposition device of the MI-TREK™ GC/MI/FTIR instrument, showing the sample delivery point and IR scan point. (Reproduced by permission of Marcel Dekker Inc. from Reedy et al.[71])

as flavor research,[77,78] lipids[79] with the benefit of analyzing free fatty acids and triglycerides using the same chromatographic column,[80] monosaccharides, mycotoxins and food additives.[71] Despite significant sensitivity improvements that have been obtained with flow cells (see Wieboldt et al.[81] for example), subnanogram detection limits have been only achieved with a DD interface that eliminates the supercritical mobile phase.[75] On-line SFC/DD/FTIR spectra have been obtained by slightly modifying the DD device used for GC/FTIR, using a window temperature close to room temperature.[75] Excellent results have been obtained with this technique in the analysis of poly(ethylene glycol)s of various average molecular weights.[45] In this mode, as with the GC/DD/FTIR interface, the spectra are obtained in the condensed state, and they may be searched against a conventional IR spectral database.

In conclusion, after this short overview of technique developments, it is clear that the use of FTIR provides sensitive detection of species eluting from a gas chromatograph, and delivers positive identification through the observation of characteristic spectral information. In particular, GC/FTIRS is able to differentiate closely related isomers, a unique feature of IR spectroscopy. Therefore, in analyzing volatile or semi-volatile compounds, GC/FTIR appears to be an essential complement to GC/MS.

ACKNOWLEDGMENTS

The Institut National de la Recherche Agronomique (INRA) and the Conseil Régional de Bourgogne are thanked for financial support. The author is indebted to Christian Giniès and Etienne Sémon for skillful operation of the GC/FTIR instruments at INRA, Laboratoire de Recherches sur les Arômes, and for interesting discussion.

ABBREVIATIONS AND ACRONYMS

DD	Direct Deposition
DDT	Dichlorodiphenyltrichloroethane

DTGS	Deuterated Triglycine Sulfate
FFT	Fast Fourier Transform
FID	Flame Ionization Detector
FTIR	Fourier Transform Infrared
FTIRS	Fourier Transform Infrared Spectrometry
GC	Gas Chromatography
GC/FTIRS	Gas Chromatography/Fourier Transform Infrared Spectrometry
GC/IR	Gas Chromatography/Infrared
GC/MS	Gas Chromatography/Mass Spectrometry
GS	Gram–Schmidt
HPLC	High-performance Liquid Chromatography
HRGC	High-resolution Gas Chromatography
IR	Infrared
LP	Light Pipe
MCT	Mercury Cadmium Telluride
MI	Matrix Isolation
MS	Mass Spectrometry
NMR	Nuclear Magnetic Resonance
PUFA	Polyunsaturated Fatty Acid
SFC	Supercritical Fluid Chromatography
SIM	Single-ion Monitoring
S/N	Signal-to-noise
SPME	Solid-phase Microextraction
TIC	Total Ion Current
WCOT	Wall-coated Open Tubular

Infrared reflection–absorption spectroscopy (IRAS, IRRAS) is an optical technique used to study thin (often submonolayer) films adsorbed on reflective substrates such as metals. Experimentally, it involves measuring the change in the reflectance spectrum of the substrate that accompanies adsorption. In order to maximize sensitivity, the reflection is usually performed at grazing incidence. On metal surfaces, the process is subject to an overriding selection rule which states that only those vibrational modes that have a component of their dipole change perpendicular to the surface can be detected: application of this metal surface selection rule (MSSR) often yields important information about adsorption geometry. Other advantages of the technique include its high sensitivity ($<10^{-4}$ monolayers in favorable instances), its ability to operate under high ambient pressures where other primarily electron-based surface spectroscopies cannot be utilized, and the ease with which its results can be correlated with those from other vibrational spectroscopies, both surface- and bulk-sensitive. A significant current disadvantage is the difficulty in studying low-wavenumber vibrations, but this is being overcome by the development of more intense far-infrared sources. Various acronyms for the technique have been employed – IRAS, IRRAS and Reflection–Absorption Infrared Spectroscopy (RAIRS) have all enjoyed wide currency. The last of these is perhaps the most widely used and is the form advocated by the International Union of Pure and Applied Chemistry (IUPAC).[1,2] Accordingly, it will be adopted in this article.

1 INTRODUCTION AND HISTORICAL OVERVIEW

The first applications of infrared spectroscopy to the study of adsorbed species date back to the late 1930s and its use to characterize supported catalysts had become well established by 1960. However, these early studies employed powdered or porous substrates with high specific areas, typically between 1 and 1000 $m^2\,g^{-1}$, which allowed milligram quantities of the adsorbed species to be introduced into the infrared beam. The 1960s witnessed the rapid development of a range of surface science probes capable of determining adsorbate structures and electronic energy levels on single-crystal and other well-defined substrates, thereby emphasizing the need for complementary techniques of vibrational spectroscopy in this area. The rather small surface area of the samples employed in surface science ($\sim 10^{-4}\,m^2$) corresponds to only nanogram masses of adsorbate in a monolayer, so sensitivity poses a much more severe problem than in the study of high area materials. Despite this, infrared sensitivity to monolayer quantities was quickly attained, initially by Pickering and Eckstrom,[3] who studied the adsorption of carbon monoxide and hydrogen on nickel and rhodium films using a multiple reflection procedure in which the incoming beam was at near-normal incidence to the surface. That such a geometry was far from optimum was recognized by Greenler,[4,5] who developed the underlying theory of RAIRS which will be described in the next section, demonstrating that sensitivity was optimized at high angles of incidence. Subsequent studies have employed glancing incidence beams, almost always using a single-reflection configuration. The first characterization of an adsorbate on a single-crystal substrate was achieved in Pritchard's laboratory at the end of the 1960s.[6] This group also pioneered the integration of RAIRS with other techniques of surface science such as low-energy electron diffraction, surface potential measurements, and various electron spectroscopies. This trend has continued and it is now normal for RAIRS instrumentation to be integrated into a system that also contains other probes to establish surface composition, structure, and topography.

Until the mid-1980s, specialized dispersive spectrometers were almost invariably used for RAIRS. Excellent signal-to-noise (S/N) ratios could be achieved over a limited wavenumber range with such instruments (corresponding to a sensitivity of less than a thousandth of a monolayer for a strongly absorbing species such as carbon monoxide). However, dispersive spectrometers are

poorly suited to rapid scanning of broad ranges of the infrared spectrum, while the specialized nature of the instruments employed in RAIRS discouraged its wider application. The use of commercial Fourier transform infrared (FTIR) spectrometers in RAIRS studies was pioneered by Chesters, who clearly demonstrated their advantages over dispersive spectrometers,[7] and FTIR instrumentation is now almost universally employed. Recent developments in RAIRS have concentrated on extending the range of application of the technique: important instances of this include extension of the wavenumber range (especially into the far-infrared, to observe vibrations of the primary chemisorptive bond between surface and adsorbate), the use of higher gas pressures to mimic industrial catalytic processes, and even studies in aqueous environments, particularly in the study of electrode reactions.

Figure 2 Resultant electric fields relative to the incident field E_0 for infrared radiation incident on a metal with optical constants appropriate to copper at 2000 cm^{-1} ($n = 3$; $k = 30$). $E_{p\|}$ and $E_{p\perp}$ are the components parallel and perpendicular to the surface which arise from initially *p*-polarized radiation. 2 PRINCIPLES

The process of reflection at a surface is most easily analyzed by considering the behavior of two polarization components, the *s* component, whose electric field is polarized parallel to the surface and perpendicular to the direction of propagation, and the *p* component, perpendicular to both the *s* component and the line of propagation (Figure 1). Radiation of arbitrary polarization can, of course, be resolved into a combination of these two components.

The process of reflection changes both the magnitude and the direction of the electric field associated with each of these components. A molecule in the vicinity of the surface thus experiences a combination (i.e. the vector sum) of the fields due to the incident and reflected beams. With metals, the direction of the *s* component is almost exactly reversed on reflection, but, since metals have high reflectivities in the infrared, its magnitude is little changed. Electric vectors $\boldsymbol{E}_s$ and $\boldsymbol{E}'_s$ are hence almost exactly equal and opposite, and therefore nearly cancel. The behavior of the *p* component depends somewhat on the angle of incidence, θ, but when θ approaches 90° (i.e. at glancing incidence), the fields combine to give a large component perpendicular to the surface and a much smaller one parallel to it. The θ-dependence of the resultant fields is shown in Figure 2. Bearing in mind that absorption intensity is proportional to the square of the amplitude of the electric field vector, it will be appreciated that at no angle of incidence is there a significant field parallel to the surface, but that an enhanced field perpendicular to the surface arises from the *p* component at angles close to grazing.

Figure 1 Electric vectors of *s*- and *p*-polarized radiation incident on a metal surface at an angle θ to the normal. Primed and unprimed vectors refer to the reflected and incident beams respectively.

There are two immediate and important consequences of this. The first is that the sensitivity is maximized by employing high angles of incidence. In this regard, the field enhancement already noted is augmented by a simple geometric factor: at glancing angles the beam covers a larger area of surface and hence more molecules. The combined effect of the two factors in a typical case is shown in Figure 3, where it can be seen that the relative sensitivity is sharply peaked at an angle close to grazing. In practice, it is usually not possible to exploit this enhancement fully, partly because the incident beam subtends a range of angles at the surface and partly because at very high angles the projected width of the beam is often larger than the sample width. Bradshaw and Schweizer[9] have shown how the enhancement depicted in Figure 3 is modified by the adoption of a more realistic experimental geometry, concluding that optimum performance should be achieved at an angle a few degrees closer to the normal than the figure would indicate. Nevertheless, the basic principle still applies and experiments are almost always performed using an angle of incidence that is fairly close to grazing.

Figure 4 Real and image dipoles at a metal surface. (a) Image effect for a single charge, (b) image of a real dipole parallel to the surface opposes original, (c) enhancement of original when dipole is perpendicular to surface. (Reproduced with permission of Elsevier Science from Pearce and Sheppard.[10])

The second consequence of the optical properties of metal surfaces arises from the fact that it is not possible to establish a large oscillating electric field parallel to the surface. Any dipole lying parallel to the surface will hence be subject to only very small variations in the electric field along its length and will therefore scarcely interact with the incident radiation. We can hence establish the MSSR as developed by Pearce and Sheppard.[10] This states that "only those modes which have vibrational dipole moments with components perpendicular to the metal surface will have measurable intensities". The original discussion of this was couched in terms of image dipole effects which are formally equivalent to the argument already given, but are perhaps easier to grasp intuitively. A famous result in electrostatics[11] states that the field due to a charge situated a distance d above a perfectly conducting plane is identical to that in which the conductor is replaced by a second charge, equal to the first but opposite in sign, placed a distance d below the plane. When this formalism is applied to the two charges that constitute a dipole above a (planar, conducting) metal surface, a clear distinction between parallel and perpendicular dipoles is evident (Figure 4). When the dipole is parallel to the surface, it is opposed by its image. Since the separation between the real and image dipoles is of molecular dimensions and accordingly much smaller than infrared wavelengths, their interactions with infrared radiation cancel essentially perfectly and no absorption can occur. Dipoles perpendicular to the surface, however, reinforce each other, and enhanced absorption is accordingly observed.

The MSSR is often of great help in interpreting RAIRS spectra. For example, at low coverages the spectrum of benzene adsorbed on the silver (100) surface exhibits a single band, whose wavenumber corresponds to that

Figure 5 RAIRS spectra of benzene adsorbed on a silver (100) surface. (a) At submonolayer coverages, showing only a band due to the out-of-plane deformation mode, (b) at multilayer coverages, with additional in-plane modes active. (D.A. Slater and P.C. Welch, unpublished work.)

of the out-of-plane deformation mode (Figure 5). This band persists as the coverage is raised to multilayers, but additional bands with wavenumbers corresponding to various in-plane stretches and deformations also appear. The interpretation of these results in terms of the MSSR is that at low coverages the plane of the molecule lies strictly parallel to the surface, so that only the out-of-plane mode is infrared active. At multilayer coverages, the appearance

of extra bands shows that the molecules are no longer all parallel to the surface. This could arise either through tilting of the molecular plane, or by the development of a structure in which some molecules remain parallel to the surface, but others are perpendicular to these: the latter case corresponds to the structure of bulk benzene and is hence the preferred explanation.

Although the MSSR is of great utility, some care must be exercised in its application. One example of this arises in the analysis of spectra from strongly polarizing species such as dioxygen. On a number of substrates oxygen has been found to adsorb molecularly in the peroxide form where the O–O bond is believed to lie strictly parallel to the surface, but where the O–O stretching vibration can nonetheless be observed. The explanation for this is that the metal–oxygen bond is strongly polar and that the charge separation in this depends on the O–O separation. When the O–O stretching vibration is excited, the changes in the O–O bond that occur during the course of the vibration engender concomitant changes in the metal–oxygen bonds, so that an oscillating dipole is established perpendicular to the surface. Since this oscillates at the same frequency as the primary O–O stretching vibration, an absorption band having the same wavenumber as the O–O stretch is observed in the RAIRS spectrum.

It has been shown that modes involving dipole changes which are strictly parallel to a metal surface can sometimes give rise to antiabsorption bands in RAIRS spectra (that is they produce increases in surface reflectivity relative to neighboring regions of the spectrum). This phenomenon, which has chiefly been observed with low-frequency frustrated translations and rotations of the adsorbed species, has been explained in terms of a model that invokes the surface resistivity which the metal conduction electrons experience.[12] Scattering of these electrons by the adsorbate molecules leads to a very broad background absorption in the infrared. However, when the frequency of the incident radiation equals the resonance frequency of a parallel mode, the molecules and the conduction electrons move together, the additional surface resistivity is eliminated, and the background absorption is reduced, leading in turn to the apparent antiabsorption feature. It has been argued that these antiabsorption resonances constitute exceptions to the MSSR, but it is perhaps more useful to envisage them simply as a consequence of an excitation mechanism different from that underlying conventional infrared absorption. Viewed in this context, they are no more exceptions to the MSSR than are the impact excitations of parallel modes observed in vibrational electron energy loss spectroscopy (VEELS) (section 3.4). In any case, since the appearance of these bands is almost precisely opposite to that of an absorption band, confusion between the two is unlikely to arise.

The chief constraint on application of the MSSR, however, is that it is valid only for highly conducting materials, as epitomized by metals. This is true for the whole of the foregoing discussion in this section. Semiconductors and insulating materials lack the high reflectivity of metals in the infrared and accordingly give rise to much weaker absorption bands. RAIRS is therefore a less useful technique for the study of adsorption on such surfaces, which are usually investigated by attenuated total reflectance or by transmission infrared spectroscopy as discussed in a review by Horn.[13] One method of applying RAIRS to such surfaces, however, is to generate (by evaporation or chemical reaction) a thin layer of nonmetal on a metal substrate. Since the wavelength of infrared radiation is long compared with the distances over which chemical interactions take place, it is possible by this means to create a surface whose chemical properties are dominated by those of the overlayer, but which behaves optically as a metal. In the case of silicon overlayers, the real part of the refractive index is close to that of many metals and layers several tens of nanometers in thickness deposited on a metal substrate exhibit optical properties that are essentially metallic in character, as Figure 6 demonstrates. Horn[13] has compared the RAIRS spectrum of a hydrided silicon surface with that of a surface prepared by depositing a silicon layer four atoms thick on a ruthenium substrate and then forming the hydride, finding that the composite substrate yields Si–H stretching bands almost an order of magnitude more intense than the pure silicon, and with a corresponding improvement in S/N ratio.

A similar procedure has been widely used to investigate adsorption on ice surfaces in order to model heterogeneous processes occurring on atmospheric ice particles that are known to be important in stratospheric chemistry. Instead of attempting to carry out RAIRS using a solid ice substrate, a thin (ca. 10 nm) layer of ice is prepared on an inert metal substrate by condensation from the vapor phase. The optical properties of the resulting compound substrate are dependent on wavelength, since ice itself shows strong absorption bands in the mid-infrared, and the design of the RAIRS experiment has to be modified to take this into account.

Returning now to metal surfaces, it might appear that the sensitivity to weakly absorbing species could be enhanced by the use of multiple reflection techniques to sample the adlayer repeatedly. As noted in the previous section, Pickering and Eckstrom[3] employed this method in the earliest RAIRS study, using a multiple reflection White's optics cell in which the mirrors served as the substrate for adsorption. However, Greenler[5] showed that this seemingly attractive possibility for improving sensitivity is limited by the imperfect reflectivity of the substrate, which results in a loss of energy at each

Figure 6 Calculated reflectance at $2000\,cm^{-1}$ of a silicon-on-copper composite interface as a function of silicon thickness and angle of incidence. Metallic behavior persists to substantial thicknesses. Calculated using a program developed by A.B. Horn.

reflection even in regions of the spectrum where the adsorbate does not absorb. In consequence, although the relative absorption intensity increases at each reflection, the absolute intensity attains a maximum after a rather modest number of reflections. If further reflections are attempted, the magnitude of the signal decreases, and, provided that detector noise is the limiting factor (as it usually is), the S/N ratio deteriorates. The number of reflections required to give the maximum signal is given by the integer closest in value to the expression in Equation (1)

$$N_{max} = \frac{\ln(\ln R_0/\ln R)}{\ln(R/R_0)} \qquad (1)$$

where R and R_0 are the reflectivities at the center of the absorption band and away from this band, respectively. Greenler showed that with most metals a single reflection will produce a large fraction (>60%) of the maximum signal theoretically attainable using multiple reflections. The experimental difficulties which attend the implementation of multiple reflection spectroscopy have accordingly been thought to outweigh the small advantages which the technique could in principle provide, at least for single crystal substrates. However, multiple reflections are sometimes employed in the study of polycrystalline materials.

The discussion so far has concentrated on the substrate and no explicit consideration has yet been given to the influence that the optical properties of the adsorbate have on the RAIRS spectrum. The pioneering paper in this area was that of McIntyre and Aspnes,[14] who obtained analytic solutions for the change of reflectance ($\Delta R/R$) for the situation in which an adlayer of thickness d and complex refractive index $n - ik$ overlies a metal substrate. Making approximations valid for submonolayer coverages of an isotropic adsorbate which is fairly weakly absorbing and for an angle of incidence θ which is not too high, these expressions yield the result in Equation (2) for the reflectance change for p-polarized radiation of wavelength λ

$$\frac{\Delta R}{R} = -\left(\frac{4\pi kd}{\lambda}\right)\left(\frac{4\sin\theta\tan\theta}{n^3}\right) \qquad (2)$$

The first factor in this equation corresponds to the familiar attenuation factor εcl in the Beer–Lambert law, while the second corresponds to the field and geometrical enhancements alluded to earlier. This part of the expression takes the same form as that derived from the situation in which the adsorbate is neglected, apart from the inclusion of the factor n^3 in the denominator. Accordingly, to take proper account of the adsorbate, the absorption intensities in Figure 3 should be reduced by this factor, but the conclusions are otherwise unchanged at this level of approximation.

Subsequent work by a number of authors has extended the calculations of McIntyre and Aspnes. Specific additions to the theory include treatment of the adsorbate as a uniaxial or biaxial medium rather than as an isotropic one, extensions to thicker or multiple films and to more strongly absorbing adlayers, consideration of a wider range of substrate optical parameters to include semiconductors and dielectrics as well as metals, and inclusion of the effects of surface roughness. The essential physics behind these calculations is simply an application of Maxwell's equations to the case of an infinite plane electromagnetic wave interacting with a layered structure, and is accordingly well understood in principle. However, as might be expected, increasing complexity of the adlayer system leads to significant computational difficulties, especially when thick multilayers of strong absorbers are being considered.

Early methods of calculation concentrated on finding analytic solutions at appropriate levels of approximation, but more recent work has favored the use of numerical simulation. A particularly comprehensive approach along

these lines has been described by Parikh and Allara,[15] who discuss procedures for the quantitative simulation of both reflection and transmission spectra from multilayer anisotropic systems. As part of its input, such a simulation requires optical parameters for each substrate and adlayer material in the form of a frequency-dependent complex refractive index or permittivity, which in the most general form for an anisotropic medium is described by a tensor quantity. One difficulty arising from this is that for many organic materials this tensor may not be known, either because the large single crystals needed to make the appropriate optical measurements are not available, or because these measurements are themselves too demanding. To circumvent this problem, Parikh and Allara also describe a means for estimating the tensor from experimental measurements made on bulk isotropic material, such as a random dispersion of small crystallites in a matrix of potassium bromide or some similar inert material.

These advanced optical methods allow the simulation of spectra from complex layered systems, such as LangmuirBlodgett and self-assembled films formed from large organic molecules. It should be noted, however, that in practice most experimental results from simpler systems can be dealt with adequately either by using the simplified theory of McIntyre and Aspnes discussed earlier, or even by giving no explicit regard to the optical properties of the adlayer.

In comparing RAIRS measurements with those from other nonsurface infrared spectroscopies, it is often convenient to express the observed intensities in terms of the magnitude of the dynamic dipole involved in the oscillation. The experimental measure of intensity for an absorption band in RAIRS is the integrated absorbance A defined by the relationship in Equation (3)

$$A = \int_{\tilde{\nu}} \ln\left(\frac{R_1}{R_2}\right) d\tilde{\nu} \tag{3}$$

where R_1 and R_2 are respectively the surface reflectivities in the absence and presence of the adsorbate, and $\tilde{\nu}$ represents wavenumber. In the general case, when the surface film has significant thickness, the relationship between this quantity and the magnitude of the dynamic dipole is complicated. However, for a submonolayer film with the dipoles oriented perpendicular to the surface, it reduces to[16] Equation (4)

$$A = \frac{1}{4\pi\varepsilon_0} \frac{4\pi^2 n_s \tilde{\nu}_p \mu^2 \sin\theta \tan\theta}{c\hbar} \tag{4}$$

Here, n_s is the adlayer density (molecules per unit area), $\tilde{\nu}_p$ the wavenumber of the peak absorbance and μ the dynamic dipole. After evaluation of the various constants, this yields Equation (5)

$$\mu = 2.985 \times 10^{-19}\text{C} \sqrt{\frac{A}{\tilde{\nu}_p n_s \sin\theta \tan\theta}} \tag{5}$$

In comparing different oscillators, it is convenient to express the dynamic dipole in terms of the effective charge which moves during the oscillation (e^*). This is given by Equation (6)

$$\mu = e^* \sqrt{\frac{\hbar}{4\pi c m_r \tilde{\nu}_p}} \tag{6}$$

where m_r is the reduced mass of the oscillator. In terms of the molar reduced mass M_r and electronic charge e, this can be expressed as Equation (7)

$$\frac{e^*}{e} = 4.538 \times 10^8 \sqrt{\frac{(A/\text{m}^{-1})(M_r/\text{g mol}^{-1})}{(n_s/\text{m}^{-2})\sin\theta \tan\theta}} \tag{7}$$

For strongly absorbing species, the value of e^* is a substantial fraction of e.

The above equations assume that the real dipole is enhanced by its image (Figure 4): values of μ and e^* twice those given by the above expressions are appropriate if this assumption is not made.

3 EXPERIMENTAL TECHNIQUES

3.1 General Considerations

The requirements for a RAIRS experiment have essentially been defined in the previous section: it is necessary to record the reflectance spectrum of the substrate with a high (S/N) ratio both before and after adsorption, and then to compare the resulting spectra. This final stage is now almost invariably achieved by digital ratioing. As Figure 3 illustrates, the angular range of the incident beam that can be effectively utilized is rather limited. This, combined with the small size of the sample, ensures that the étendue (the conserved product of image size and the solid angle subtended) is much smaller than in most other applications of infrared spectroscopy: values between 10^{-1} and 10^{-2} mm^2 sr are typical. This has implications for the design of the experiment, particularly in terms of the types of source and detector that are appropriate.

The sensitivity of RAIRS is obviously dependent on the attainable noise levels. These are typically in the region of a few parts in 10^5 throughout most of the infrared spectrum, although in the region below about 600 cm^{-1} special sources are needed to achieve this, as will be discussed in section 3.2. This noise level corresponds to

a sensitivity of about 10^{-4} monolayers in the case of adsorbates with particularly strong infrared absorption bands (of which carbon monoxide is the archetype). In less favorable cases, such as the rather weakly absorbing C–H stretching vibrations of hydrocarbons, sensitivity is reduced to a value typically in the range 10^{-2} to 10^{-1} monolayers.

In comparison with many other techniques of surface science, RAIRS possesses the considerable advantage that the probe photon can propagate through nonvacuum environments. This enables the spectrometer to be set up outside the ultra-high vacuum (UHV) chamber, which considerably simplifies operation: not only can materials incompatible with UHV environments be used in construction, but repair and maintenance are facilitated by the absence of any need to break the vacuum in order to perform them. The only modification that is required of the UHV chamber itself is the addition of suitable infrared-transmitting windows. Sapphire or calcium fluoride windows were frequently used during the period when RAIRS was being developed, since they are robust, nonhygroscopic, and available commercially already mounted in UHV-compatible flanges. More recently, alkali halide windows (sodium chloride, potassium bromide, or cesium iodide) have been preferred because of their wider transmission range and, in the first two cases, lower cost. The thermal expansion coefficients of these materials are much higher than that of stainless steel and compensation must be made for this to avoid failure of the window when the UHV system is baked. The usual procedure is to mount the window between O-rings made from a high-temperature elastomer such as Viton, with UHV-compatibility being achieved through differential pumping between these and another O-ring sealing against atmosphere.[17] The alkali halides are also hygroscopic and must be protected against excessive exposure to moist air. Potassium bromide windows permit operation down to 400 cm^{-1}, while the cut-off for cesium iodide lies below 200 cm^{-1}. Cesium iodide is much softer than potassium bromide, but this may prove advantageous in some circumstances, since mechanical or thermal shock is likely to be accommodated by the material deforming, rather than suffering a potentially much more serious fracture.

For many applications, the ideal infrared window material is diamond, which combines great strength with chemical inertness and excellent thermal properties. To obtain good transmission in the infrared, clear diamonds of low nitrogen content (designated as Type IIA diamond) must be used. Until recently, these have been prohibitively expensive in the sizes required for RAIRS applications, but the increasing availability and rapidly diminishing cost of large synthetic diamonds prepared by chemical vapor deposition (CVD) is changing this situation. Natural Type IIA diamonds and CVD diamonds exhibit essentially identical infrared spectra:[18] both are highly transparent throughout the whole of the infrared region (and, indeed, through much of the ultraviolet (UV) and X-ray region), but they do show some absorption around 2000 cm^{-1}. However, this absorption is relatively weak and can be minimized by the use of very thin windows which, because of diamond's great strength, can still support a differential pressure of an atmosphere. The high refractive index of diamond (2.4) necessitates the use of windows mounted at the Brewster angle if excessive losses through reflection are to be avoided.

Although infrared radiation is much more tolerant of gas-phase species than other surface probes such as electrons, it is obviously advantageous to eliminate any such species that exhibit very strong absorption bands. In studies in the mid-infrared region of the spectrum, it is usual to remove water vapor and carbon dioxide from the spectrometer by purging it with air that has been passed through appropriate molecular sieve filters to remove these gases. In the far-infrared, water vapor is particularly troublesome and the use of vacuum spectrometers (operating at about 10^{-2} mbar) is generally advocated.

Until the mid-1980s, almost all RAIRS experiments were performed using dispersive spectrometers, often extensively modified in order to optimize performance. Various techniques were used to improve these spectrometers, including wavelength modulation, polarization modulation, double-beam spectroscopy, and infrared ellipsometry. These methods have been reviewed in some detail elsewhere.[8] Polarization modulation and infrared ellipsometry both achieved an improvement in performance by utilizing the difference in behavior of *s*- and *p*-polarized radiation to obtain an effective double-beam effect, while wavelength modulation produced a signal proportional to the derivative of the conventional spectrum, thereby emphasizing sharp spectral features such as adsorbate absorption bands. More recently, however, these specialized dispersive instruments have been almost entirely displaced by FTIR spectrometers, which are often applied to RAIRS studies with little or no modification of the standard commercial instrument. Nevertheless, there are indications that readoption of now rarely used techniques may prove valuable for some applications, particularly for studies at relatively high gas pressures, where infrared absorption by the phase surrounding the sample is significant. This topic will be considered again in section 3.3.

An extreme case of absorption of infrared radiation by the medium surrounding the surface under study occurs in aqueous solutions, where variants of RAIRS have been widely employed to study adsorption and reaction at

metal electrode surfaces.[19] Two different techniques are usually combined in order to record spectra from surfaces immersed in water, which exhibits very strong infrared absorption bands. First, the path length through the water is minimized by placing the surface very close to the infrared-transmitting window. Separations of the order of micrometers are often used, and prismatic windows are employed in order to achieve the optimum high angle of incidence at the sample. The short path length though the water permits a reasonable proportion of the infrared radiation to be transmitted, but the absorption bands are still strong and would normally swamp any bands due to submonolayer quantities of adsorbate, so an additional means of discriminating against liquid-phase absorption is required. This is achieved by varying the potential applied to the electrode in order to disrupt and reform the adlayer. If, as is usually the case, the infrared spectrum of the liquid phase is unchanged by this change in potential, then the difference between spectra recorded at the two potential differences corresponds to the difference between the surface spectra at these potentials. Spectra from electrodes were first recorded at high sensitivity using a method known as EMIRS (electrochemically modulated infrared spectroscopy) which employed a dispersive spectrometer operating at a slow scan rate in conjunction with a relatively rapid (several hertz) modulation of the potential. As FTIR spectrometers began to supplant the dispersive variety, this was largely replaced by SNIFTIRS (subtractively normalized interfacial Fourier transform infrared spectroscopy), in which a series of scans are taken to obtain a spectrum at a particular potential, the potential is changed, and a second spectrum then recorded. The rapid modulation used in EMIRS is particularly effective in eliminating the effects of drift, and very high S/N ratios are attainable, allowing reflectance changes to be detected at the part per million level. The ultimate sensitivity of SNIFTIRS is somewhat poorer than this, but this disadvantage is usually outweighed by the greater range of potentials that can be employed: while EMIRS is restricted to the study of systems oscillating between two stable configurations, SNIFTIRS can be used to monitor the changes accompanying irreversible voltammetric reactions.

In conventional infrared spectroscopy, FTIR spectrometers exhibit three well-known advantages over scanning dispersive instruments.[20] The first of these, the Fellgett or multiplex advantage, derives from the fact that the spectrometer samples the whole spectral range simultaneously, while a scanning instrument can sample only one resolution element at a time. The measurement time for a spectrum at a given S/N ratio is accordingly reduced by a factor equal to the number of resolution elements, N (numerically equivalent to the width of the spectral range being scanned divided by the resolution). Alternatively, given a fixed measurement time, the S/N ratio is improved by a factor equal to the square root of N. Since N is typically of the order of 10^3, the advantage is generally substantial. In RAIRS, where one seeks to measure a very small change in the signal, the multiplex advantage applies, although it imposes considerable demands on the dynamic range of the spectrometer's detector and analog-to-digital converter (ADC) which will be discussed further in section 3.3.

The second advantage of FTIR spectroscopy, the Jacquinot or throughput advantage, arises because slits are not required in the spectrometer to define a resolution element. Hence, the throughput, or radiation flux, through an FTIR instrument is higher than through a dispersive one, especially at high resolution. In RAIRS, where the small sample size defines a low étendue, it might be expected that the throughput would always be limited by the sample, even with a dispersive spectrometer, and that the Jacquinot advantage would therefore not apply. However, Bradshaw and Schweizer[9] have demonstrated that while this is likely to be true for measurements in the far-infrared, it is often not so in the mid-infrared. They calculate that when using a standard dispersive instrument incorporating a monochromator of 300 mm focal length, the slits rather than the sample become throughput-limiting when the resolution reaches $4\,cm^{-1}$, and that the Jacquinot advantage will accordingly apply at higher resolutions. Allied to the Jacquinot advantage is the observation that when using an FTIR spectrometer, the resolution can be improved simply by increasing the distance through which the moving mirror of the interferometer travels, without otherwise changing the optical arrangement. With a dispersive instrument, the equivalent procedure of reducing the slit width is inevitably more complicated and frequently requires subsequent realignment of the optical path in order to optimize the signal.

The third well-known advantage of FTIR spectrometers, the Connes advantage, relates to the internal calibration of the wavenumber scale provided by the spectrometer's helium–neon laser, and is obviously relevant to RAIRS operation.

As well as these advantages which apply to all areas of infrared spectroscopy, FTIR spectrometers have conferred at least two benefits specifically to RAIRS. The first is the ability to scan an extended wavelength range in a single spectrum. Although the best S/N performance achieved using dispersive spectrometers was probably as good as that subsequently attained by FTIR, it was necessary to optimize the spectrometer for a limited wavenumber range, typically less than $200\,cm^{-1}$ in width. Operation outside this range required grating and filter changes which were time-consuming and, in practice,

rarely performed. Only after the introduction of FTIR technology to RAIRS did the scanning of a wide spectral range become in any way routine. The second benefit derives from the fact that FTIR instruments sample all spectral elements simultaneously. With dispersive spectrometers, the limiting S/N performance was often imposed not by the short-term performance of the detector and its associated electronics, but by much longer-term drifts in detector sensitivity, source temperature, optical alignment, and similar factors. The techniques applied to improve the performance of dispersive spectrometers, particularly wavelength and polarization modulation, achieved their effect mainly by minimizing the influence of these drifts. With FTIR spectrometers, however, such drifts affect all parts of the spectrum almost equally and special techniques are not required to reduce them.

3.2 Infrared Sources

In the vast majority of RAIRS investigations, conventional thermal sources have been used. Such sources are typified by the globar, a silicon carbide rod which is heated resistively, usually to between 1100 and 1500 K, when it behaves as a near-perfect gray body (i.e. constant emissivity) source. Operated in this way, the globar maintains high intensity levels throughout the mid-infrared region between 1000 and 4000 cm^{-1}. It also has sufficient thermal inertia to ensure that it is not overly sensitive to short-term fluctuations in its cooling, and subject to the obvious condition that its power supply must be adequately stabilised, it generally gives good performance in this spectral region, although higher-temperature sources (e.g. a tungsten ribbon at approximately 3000 K) are sometimes preferred at the high wavenumber end of the range.

As one moves toward lower wavenumbers, however, thermal sources become increasingly inadequate, to the extent that few RAIRS studies have investigated the range below 600 cm^{-1}. The reason for this lies in the form of the blackbody radiation curve, as Figure 7 illustrates. It is clear that while the total output integrated over all wavelengths rises very rapidly with temperature (as T^4, following the Stefan–Boltzmann law), the bulk of this additional power is concentrated in the high wavenumber region and intensity at low wavenumbers never approaches that in the mid-infrared. Indeed, in the longwave Rayleigh–Jeans limit the intensity is proportional only to T. Since the output of a 3000 K source is approximately 30 times greater at 2000 cm^{-1} than at 300 cm^{-1}, reasonable power at the lower wavenumber could be obtained from a thermal source only at temperatures in the vicinity of 10^5 K which are obviously unattainable in practice. In many applications of infrared spectroscopy, this loss of intensity at longer wavelengths can be offset by increasing the source size (i.e. étendue), but as already noted, the narrow angular spread of the usable beam in RAIRS reduces the available étendue to a low value, typically in the range 10^{-2}–10^{-1} mm^2 sr. Since increasing the source size is not an effective strategy, a means must be found to increase the absolute brilliance (i.e. power per unit étendue) of the source.

Several groups have now attained this brilliance by the use of synchrotron radiation from a storage ring. Although synchrotron radiation is normally considered as a source of short wavelength radiation (X-rays and vacuum UV), it does contain a significant component in the far-infrared. For example, the synchrotron radiation source at the Daresbury Laboratory, England, operating

Figure 7 Intensity per unit wavenumber interval for a blackbody source at the temperatures indicated. (a) In the mid-infrared, (b) in the far-infrared.

Table 1 Relative intensity of the Daresbury SRS in comparison with a 1500 K blackbody as a function of wavenumber and the experimental étendue[a]

Étendue (mm^2 sr)	Wavenumber (cm^{-1})			
	3300	1000	330	100
1	0.02	0.08	0.45	4.5
10^{-1}	**0.27**	**0.75**	**4.5**	**45**
10^{-2}	**2.7**	**7.5**	**45**	**450**

3.5×10^{-4}	81	210	450	450
10^{-4}	270	450	450	450

[a]Entries in bold are typical for a RAIRS experiment.

with an electron current of 300 mA at 2 GeV, has an output in the far-infrared equivalent to that of a blackbody source at a temperature in excess of 650 000 K, about 450 times that of a globar.[21] However, the effective size of the source varies with wavelength, and in the near-infrared the available étendue is small even by the standards of RAIRS, so that thermal sources can actually deliver more power. As one moves toward longer wavelengths, the source étendue increases, and the storage ring starts to deliver more power than a thermal source. Table 1 shows the relative performance of the Daresbury source against a 1500 K blackbody as a function of wavenumber for a range of experimental étendues. Recalling that the relevant range for RAIRS is approximately 10^{-2} to 10^{-1} mm^2 sr, it is seen that the advantage over the thermal source first becomes evident at about 1000 cm^{-1}, that this advantage has increased to approximately one order of magnitude at 330 cm^{-1}, and reaches a limiting value close to 450 at the longest wavelengths, in accordance with the effective blackbody temperature of the synchrotron source.

Infrared beamlines for RAIRS applications are now in operation at several storage rings, with many others under construction.[22] The possibility of extending the technique to longer wavelengths has a number of potential applications, but the one that has been exploited most to date is that of studying the vibrations of the primary chemisorptive bond between substrate and adsorbate. Except in the special case of the lightest atom, chemisorbed hydrogen, these vibrational features usually lie below 700 cm^{-1} and are hence difficult to observe using conventional sources. They are of course especially important in the case of atomic adsorbates, where the atom–substrate bond is necessarily the only one. The chemistry of atomic adsorbates is of major significance in catalysis, since heavy adatoms in the third and subsequent rows of the periodic table – such as sulfur, chlorine, and potassium – are widely recognized to act as poisons or promoters in a great variety of catalytic reactions. Figure 8 shows the first recorded infrared spectrum of such a heavy atomic adsorbate, chlorine on the silver (100) surface, recorded using synchrotron radiation. Other potential topics of interest in the far-infrared include the stretching modes of molecules containing heavy atoms (such as halides and the organometallics employed in semiconductor device fabrication and CVD processes), surface phonons (and their coupling with adsorbed species), and deformation modes, including frustrated rotations and translations.

Certain technical problems attend the use of synchrotron sources for RAIRS, especially in high-energy storage rings, where the electrons have kinetic energies in excess of 1 GeV. Since such kinetic energies are equivalent to several thousand times the rest mass of the electron, major relativistic effects arise. One consequence of these is that length contraction in the direction of motion results in a strongly directional beam throughout most of the electromagnetic spectrum: beam divergence in the X-ray region is less than one milliradian. In the infrared region, however, the source size is comparable with the wavelength, so that diffractive spreading increases the beam divergence to several tens of milliradians. In order to capture this beam using optical components of reasonable size, a mirror must be placed close to the tangent point where the electrons emit the synchrotron radiation: in the Daresbury beamline this mirror is 1.08 m from the tangent point. However, at this distance very little spreading of the

shorter wavelength X-ray and UV radiation has occurred, so the central region of the mirror is exposed to a very high flux of these components, leading to massive thermal loads. At Daresbury, these are overcome partly by integral water cooling of the mirror and partly by inserting a cooled stop of copper piping into the beam path immediately before the mirror (Figure 9). (Other solutions are possible and a particularly attractive one which is being explored is the possibility of cutting a central hole in the mirror through which the short-wavelength radiation passes to be utilized elsewhere: hence a single beamline could serve as a combined X-ray/infrared source.) After deflection by this primary mirror, the beam is focused by an ellipsoidal mirror onto a Brewster-angle diamond window which separates the UHV of the storage ring from the RAIRS system.

As well as high intensity in the far-infrared, synchrotron sources possess other potential advantages. The radiation is strongly polarized in the plane of the ring and so can be delivered to the sample as almost pure *p*-polarized radiation. The electrons are also distributed around the ring in evenly spaced ''bunches'' with gaps between them. This results in the emitted radiation having a temporal structure on the nanosecond scale that has potential applications for time-resolved studies, although this has yet to be exploited.

High intensity, polarization, and temporal structure are, of course, major advantages of lasers, which also emit a highly collimated beam that would allow the sharply peaked intensity curve of Figure 3 to be exploited to the full. It is perhaps surprising, therefore, that lasers have not been more widely employed in RAIRS. Attempts to use them have in fact been made by several groups, but the results have generally been inferior to those obtained with thermal sources and have been achieved only with a marked increase in the complexity of the experiment. Although lasers can now offer adequate tunability throughout the infrared region, together with much higher powers than either thermal or synchrotron sources, attaining sufficient stability for RAIRS studies appears to pose major difficulties. However, the potential advantages of lasers are so great that it seems very likely that in the long term these difficulties will be overcome.

3.3 Spectrometer Design

As already noted, most RAIRS work is now carried out using standard commercial FTIR spectrometers with minimal modifications made to accommodate the reflection experiment, which is most commonly carried out with the sample housed in a (relatively large) UHV chamber equipped with facilities for a range of other surface science techniques. Typical chamber and infrared window dimensions constrain the experimental optics to an aperture of f/5 or less, corresponding to an acceptance angle of no more than 12°, but this angle is sufficient to encompass the peak in the surface intensity function (Figure 3). Consideration must also be given to the optical arrangement used to extract the infrared beam from the spectrometer, focus it into the UHV chamber, reflect it from the surface under study, and then refocus it onto the detector. The most usual configuration, shown in Figure 10(a), involves deflecting the beam, after passage through the interferometer, out of the external port with which most commercial FTIR spectrometers are fitted. A (usually parallel) beam of radiation exits the spectrometer from this port and is focused onto the sample using either an alkali halide lens or an arrangement of mirrors. (Use of a lens affords a cheap solution which also allows a particularly simple optical path to be employed, but it suffers from chromatic aberration together with transmission and reflection losses.) After reflection from the surface, the beam is refocused onto an external detector whose signal is fed back into the processing circuitry of the spectrometer. One disadvantage of this configuration is that visual alignment of the optical path external to the spectrometer may be difficult, since the beam splitters used in mid-infrared FTIR instruments often have relatively poor transmission of visible light, while far-infrared beam splitters are frequently totally

Figure 10 Alternative optical arrangements for performing RAIRS. (a) Source-interferometer-sample-detector, (b) source-sample-interferometer-detector. S, source; I, Michelson interferometer; L, alkali halide lens (or equivalent mirror assembly); W, window to UHV chamber; X, single-crystal sample; D, infrared detector.

opaque in the visible. A common solution is to align the beam visually using a near-infrared quartz beam splitter, which transmits well in the visible, and then to replace this with the appropriate mid- or far-infrared beam splitter for spectroscopic measurement. Alternatively, a sensor card which emits visible light when struck by infrared radiation can be used, but the UHV environment near the sample usually ensures that the sensor card cannot be used in just that section of the optical path where alignment is most critical.

An alternative arrangement that avoids this difficulty is to place the source immediately before the sample and to focus the beam reflected from the sample directly into the interferometer/detector section of the spectrometer, as illustrated in Figure 10(b). The beam at the sample position is then much brighter visually. The chief disadvantage of this design compared with that in Figure 10(a) is that the (cooled) detector receives more thermal infrared emission from the (room temperature) beam splitter. Particularly when working in the far-infrared, the magnitude of this spurious beam splitter emission may be comparable with the true signal and a degradation in performance results. The problem is greatly exacerbated by the fact that commercial FTIR spectrometers are designed for high optical throughput, with an experimental étendue at least an order of magnitude greater than that of a typical RAIRS experiment. Hence, the acceptance angle of the detection optics is large and more radiation is accepted from the beam splitter than is necessary. Reduction of the detector acceptance angle to optimize it for RAIRS experiments would virtually eliminate the problem of beam splitter emission, but this has rarely been attempted.

Chesters[7] and Bradshaw and Schweizer[9] have discussed the constraints placed on a RAIRS spectrometer by the requirement for a high dynamic range. RAIRS differs from many applications of infrared spectroscopy in that it involves detection of a very small change in signal level: the reflectance change following adsorption is usually less than 1% and in some applications may be less than 0.01%. With dispersive instruments, each spectral element is collected separately, so that detection of a 0.01% band requires an S/N ratio of 10^4. With FTIR instruments, a large number, N, of spectral elements are monitored simultaneously and the change in signal is spread over all of these elements. In the absence of the multiplex advantage, this would require an increase in S/N by a factor of N to attain the same sensitivity, but since the whole interferogram contributes to the signal at any point, this factor is reduced to the square root of N. Even so, the required S/N is much higher than with a dispersive instrument: scanning a range of $3200\,\mathrm{cm}^{-1}$ at a resolution of $2\,\mathrm{cm}^{-1}$ generates 1600 spectral elements, so the S/N ratio has to be improved by a factor of 40, to 4×10^5 in the case just discussed.

Such high ratios are achieved by co-adding a large number of individual scans, each with a much poorer S/N value. The FTIR spectrometers used are accordingly rapid-scan instruments with which a single interferogram can be recorded in a fraction of a second. Attention must also be paid to the resolution of the spectrometer's ADC. In the earliest applications of FTIR to RAIRS, 15- or 16-bit ADCs were typically used. Since in normal operation of an FTIR instrument the last two bits (at least) of the ADC contain only noise,[20] the attainable S/N in a single scan from such an instrument is limited by the performance of the ADC alone to a value of about $(2^{13}/\sqrt{1600}) \approx 200$. Improvement of this to the desired value of 10^4 would then require the co-addition of approximately $(10^4/200)^2 = 2500$ scans. This number may be reduced by using ADCs of 20-bit or higher resolution which are found in more modern research instruments.

The infrared detector, too, must be able to support this high dynamic range. Most RAIRS investigations in the mid-infrared range currently use liquid nitrogen cooled mercury cadmium telluride (MCT) detectors, which have high saturation levels so that their dynamic range does not often prove limiting. MCT detectors give good performance over a wide wavenumber range, their performance at long wavelengths having improved dramatically in recent years, but for studies in the far-infrared (including especially the synchrotron work described in the previous

section), they are usually replaced either by copper-doped germanium photoconductive detectors, or by bolometric detectors fabricated from heavily doped silicon or germanium. All these far-infrared detectors require cooling to liquid helium temperatures. If the investigation is restricted to the relatively near infrared (above about $1900\,cm^{-1}$), then the liquid nitrogen cooled indium antimonide detector has a small performance advantage over the MCT.

Interaction with the underlying surface broadens the linewidths of bands in an adsorbate spectrum, typically to several reciprocal centimeters or more. There is thus no requirement for particularly high spectroscopic resolution in RAIRS work. Most experiments are carried out at $2\,cm^{-1}$ or poorer resolution, although in studies of lineshape analysis it may be necessary to reduce this to $1\,cm^{-1}$ or $0.5\,cm^{-1}$.

Although one of the strengths of RAIRS is the ease with which it can be added to an existing UHV apparatus without the need for major modification of either the vacuum system or the spectrometer, there are occasions when changes to one or both of these are required in order to exploit a particular advantage of the technique. One such advantage of RAIRS over many other surface spectroscopies – especially those which use electrons or ions as the surface probe – is that the interaction of the infrared photon with gas-phase species is relatively weak. RAIRS can therefore be used to study surfaces in the presence of relatively high ambient pressures of gases, and even serve as an in situ probe under reaction conditions. It thus possesses the potential to bridge the ''pressure gap'' between the UHV conditions required for the preparation of clean surfaces and the superatmospheric pressures employed in many commercial processes such as catalysis. To exploit this possibility, several researchers have modified a UHV system by the addition of a high pressure RAIRS cell, so that a sample can be prepared and characterized under UHV conditions and then transferred, still under UHV, to the cell, where RAIRS experiments can be performed over a wide pressure range. For example, McDougall and Yates[23] have described a design of cell in which RAIRS experiments can be carried out at pressures of up to two atmospheres (1 atmosphere = 101.325 kPa), far beyond the range of most other surface-sensitive techniques, and they have used this to investigate the reaction of a surface ethylidyne species ($\equiv C-CH_3$) with high pressures of hydrogen. The complete inactivity of gas-phase hydrogen toward infrared absorption, of course, makes this a particularly favorable choice for high-pressure experiments, but such studies are possible even with infrared-active gases. One way of achieving this is to monitor the absorption of both *s*- and *p*-polarized radiation separately: the two components interact equally with any gas-phase species present, but the *s* component is virtually inactive toward species adsorbed on a metal surface (Figure 3), so that the difference in absorption between the two components yields the surface spectrum. By using this approach Judd et al.[24], who also describe an alternative design of high-pressure RAIRS cell, were able to measure the spectrum of submonolayer coverages of carbon monoxide on a nickel surface under carbon monoxide pressures so high that the conventional RAIRS spectrum was swamped by absorption from gas-phase carbon monoxide and from nickel carbonyl generated by the reaction between this and the metal. The spectrometer used in this study was a comparatively primitive dispersive one which only allowed the different polarization components to be measured sequentially, rather than simultaneously, but several groups are working on more sophisticated designs. The techniques of polarization modulation and infrared ellipsometry, which were employed to improve the performance of early dispersive spectrometers but fell into disuse after the widespread adoption of FTIR technology, can measure spectra from *s*- and *p*-polarized radiation simultaneously. There is a strong likelihood that attempts to model catalytic systems at high pressure will lead to the design of FTIR instruments modified to allow some form of polarization-dependent spectroscopy. Whatever technique is adopted, the potential applications of such studies are so diverse and important that they are sure to play a major part in the future development of RAIRS.

Data acquisition times for modern FTIR spectrometers are sufficiently short to allow measurement of the kinetics of some surface processes.[7] This was exploited by Reutt-Robey et al. in an extremely elegant molecular beam experiment which monitored the diffusion of carbon monoxide molecules on stepped platinum surfaces.[25] The spectrometer was configured to scan and store individual interferograms rapidly (at up to 46.5 Hz, limited by the mechanical turn-round time of the moving mirror). Just before the start of one of these scans, the spectrometer initiated, via an RS-232 interface, a rapid (600 μs) pulse of carbon monoxide from the solenoid-actuated supersonic molecular beam doser. This pulse was adsorbed by the stepped platinum crystal surface to give a low surface coverage (~1% of a monolayer) which was initially randomly distributed between the available adsorption sites, but which diffused over time to occupy the thermodynamically favored step sites preferentially. Since molecules adsorbed on the different types of adsorption site exhibit different C–O stretching frequencies, the infrared spectrum can be used to monitor this diffusion process. By recording the proportions of the two species over timescales from a few milliseconds to an hour, and repeating these measurements over a range of substrate temperatures, the activation energy and pre-exponential factor for the surface diffusion process were determined.

Figure 11 Liquid-helium cooled spectrometer designed for RAIRS and infrared emission measurements. (Reproduced with permission of Elsevier Science from Brown et al.[26])

The most radical redesign of a UHV system and FTIR spectrometer for RAIRS applications must surely be that described by Brown et al.[26] Although primarily designed for measurements of infrared emission and chemiluminescence, this system also served, after the addition of potassium bromide windows, for more conventional RAIRS studies. The design was predicated on the need to reduce spurious thermal signals (alluded to earlier in this section in the context of beam splitter emission) to negligibly low values. To this end, the entire optical path between sample and detector (Figure 11) is shrouded in a light-tight enclosure cooled by liquid helium. The optics of the FTIR spectrometer are also cooled to liquid helium temperatures, and since operation of a laser within the cryogenic enclosure would lead to unacceptable heat dissipation, the position of the moving mirror is sensed capacitatively. The detector for the most sensitive experiments planned is a cadmium-doped germanium bolometer operating at a temperature of 0.3 K and exhibiting noise levels two orders of magnitude lower than those of a typical MCT detector. However, the saturation level of such an ultrasensitive detector is very low, so a more conventional bolometer, with a working temperature of 4 K, is used to measure higher infrared fluxes.

3.4 Comparison with other Surface Spectroscopic Techniques

A range of other techniques are capable of providing vibrational spectroscopic information from the same types of surfaces as RAIRS. The relative advantages and disadvantages of the most important of these are discussed below.

Perhaps the most directly comparable technique is VEELS,[27] which, like RAIRS, has been widely used for fundamental studies of single crystal surfaces. Energy loss spectra are recorded by reflecting a beam of monoenergetic electrons from a surface and then analyzing their energies. Most electrons are scattered elastically, but some (typically, a few per thousand) lose energy to vibrational transitions in the adlayer; a plot of the number of electrons scattered versus their energy loss constitutes the VEELS spectrum, which contains essentially the same information as an infrared spectrum. VEELS rose to prominence in the late 1970s, largely as a result of developments made by Ibach, and at that time it was the only technique capable of recording the entire vibrational spectrum of an adlayer in a single scan. The use of FTIR instruments has since then allowed RAIRS to achieve this also, so the relative merits of the two techniques now lie in other areas.

The relative sensitivities of VEELS and RAIRS are very similar (assuming equal measurement times) in the mid-infrared region, but VEELS has a definite advantage in the far-infrared. This stems not only from the poor intensity of thermal infrared sources in this region (section 3.2), but also from the fact that the performance of most VEELS spectrometers improves at low loss energies. The angular spread of the scattered electrons is smaller at these energies, so the analyzer accepts a

larger number of them, provided that this angular spread remains greater than the acceptance angle, as is usually the case. This effect causes the collection efficiency to scale as $\tilde{\nu}^{-2}$, where $\tilde{\nu}$ is the wavenumber of the loss peak.

For many years, VEELS could only achieve a much poorer spectroscopic resolution than RAIRS, being limited to several tens of reciprocal centimeters. However, Ibach then showed that reduction of space–charge effects in the spectrometer could improve this markedly[28] and spectrometers capable of achieving resolutions of a few reciprocal centimeters are now available commercially. On this basis, RAIRS still maintains a slight advantage, but not nearly to the same extent as formerly. Achievement of high resolution in VEELS, however, is critically dependent on having a well-ordered surface. If the surface becomes poorly ordered (which can happen even with a single-crystal substrate if the adsorbate does not form a well-order overlayer), then scattering becomes more diffuse and it may be necessary to degrade the resolution markedly in order to obtain an acceptable intensity.

The energy-loss process central to VEELS can occur via several mechanisms. The most important of these, dipolar scattering, is formally equivalent to the absorption of an infrared photon, and so obeys the same selection rules, including specifically the MSSR. Other significant mechanisms include impact scattering, which is a shorter-range process than dipole scattering, and negative-ion resonance excitation, which involves the capture of the incident electron by a surface or adsorbate atom, followed by the decay of the negative ion formed in this process. Impact scattering and negative ion resonance are bound by different selection rules from those applicable to dipolar scattering, and the angular distribution of the scattered electrons is also different. VEELS can therefore detect vibrational modes that are inactive in RAIRS and, moreover, it is possible by varying the experimental geometry to establish which of these modes are dipole-allowed and which are not. In some circumstances this additional information can be of considerable use in interpreting the spectrum.

One final area of comparison, where RAIRS certainly maintains an advantage, is in the pressure range over which the techniques can be applied. VEELS, relying as it does on the electrons having sufficiently long mean free paths to travel between the spectrometer and the sample, cannot be employed at pressures much above 10^{-6} mbar (even when the surrounding gas is infrared-inactive), whereas RAIRS has been used at pressures more than nine orders of magnitude higher.

Among photon-based spectroscopies, the most obvious alternative to infrared is probably Raman spectroscopy. Since Raman scattering cross-sections are typically very much smaller than infrared absorption cross-sections, the technique would seem to have a clear disadvantage in sensitivity, but submonolayer sensitivity was achieved using then state-of-the-art technology in the mid-1980s.[29] Prior to that, the observation of surface enhanced Raman scattering (SERS) caused great excitement when it was found that adsorbates on certain surfaces exhibited Raman scattering cross-sections which were typically four to six orders of magnitude greater than expected from the gas-phase cross-sections. Although it has now been established that SERS effects of this magnitude occur only on a limited range of substrates (mainly roughened surfaces of the coinage metals) and there is still some doubt as to whether the molecules enhanced by SERS are representative of the adlayer as a whole, research in the area remains active. In studies of electrode surfaces, where the beam has to be transmitted through aqueous solution, the low Raman scattering cross-section of water offers a potentially large advantage over RAIRS.

Infrared emission spectroscopy, in which the thermal radiation emitted by the adsorbate is measured directly, was used in the mid-1980s by Richards's group at Berkeley to obtain an infrared spectrum of the metal–CO stretching vibration from an extended substrate, before RAIRS had attained sufficient sensitivity to observe such vibrations in the far-infrared.[30] The apparatus used in these studies was remarkably simple, consisting of a dispersive spectrometer recording the spectra in direct current (i.e. unmodulated) mode. As with the Cambridge instrument described earlier,[26] the optics were maintained at liquid helium temperatures and the region between the (room temperature) sample and the spectrometer was screened with cold baffles. Since the blackbody radiation curve for samples at moderate (close to room) temperature peaks at a few hundred reciprocal centimeters, emission spectroscopy is most sensitive to vibrations in this range. As already noted, attempts are currently in progress to develop the technique using more modern instrumentation.

Another vibrational technique that is experiencing rapid development is sum frequency generation (SFG), in which the surface is simultaneously illuminated with a tunable infrared laser and a fixed frequency visible laser.[31] When the frequency of the infrared laser matches that of an appropriate vibration of the adsorbate, coherent anti-Stokes Raman scattering leads to resonant scattering at a frequency equal to the sum of the two laser frequencies. Although experimentally complicated, SFG has two substantial advantages as a surface probe. First, by using a pulsed laser, it offers the prospect of time-resolved measurements on a much more rapid scale than can be achieved by RAIRS. Second, the SFG process does not occur in a centrosymmetric medium, so the technique is inherently specific to the interface between two such media. It therefore offers particular scope for

the investigation of interfaces surrounded by liquids or high pressure gases and, as with Raman spectroscopy, has a potentially large advantage over RAIRS for studies of surfaces in aqueous solution.

ACKNOWLEDGMENTS

I am grateful to Dr David Slater and Dr Philip Welch for recording the spectra shown in Figure 5, and to Dr Andrew Horn for providing me with the program used to generate Figure 6.

The vibrational spectrum of a molecule is considered to be a unique physical property and is characteristic of the molecule. As such, the infrared spectrum can be used as a fingerprint for identification by the comparison of the spectrum from an ''unknown'' with previously recorded reference spectra. This is the basis of computer-based spectral searching. In the absence of a suitable reference database, it is possible to effect a basic interpretation of the spectrum from first principles, leading to characterization, and possibly even identification of an unknown sample. This first principles approach is based on the fact that structural features of the molecule, whether they are the backbone of the molecule or the functional groups attached to the molecule, produce characteristic and reproducible absorptions in the spectrum. This information can indicate whether there is backbone to the structure and, if so, whether the backbone consists of linear or branched chains. Next it is possible to determine if there is unsaturation and/or aromatic rings in the structure. Finally, it is possible to deduce whether specific functional groups are present. If detected, one is also able to determine local orientation of the group and its local environment and/or location in the structure. The origins of the sample, its prehistory, and the manner in which the sample is handled all have impact on the final result. Basic rules of interpretation exist and, if followed, a simple, first-pass interpretation leading to material characterization is possible. This article addresses these issues in a simple, logical fashion. Practical examples are included to help guide the reader through the basic concepts of infrared spectral interpretation.

1 INTRODUCTION

The qualitative aspects of infrared spectroscopy are one of the most powerful attributes of this diverse and versatile analytical technique. Over the years, much has been published in terms of the fundamental absorption frequencies (also known as group frequencies) which are the key to unlocking the structure–spectral relationships of the associated molecular vibrations. Applying this knowledge at the practical routine level tends to be a mixture of art and science. While many purists will argue against this statement, this author believes that it is not possible to teach a person to become proficient as an interpretive spectroscopist by merely presenting the known relationships between structure and the observed spectra. Instead, the practical approach, which has been adopted in this text, is to help the reader appreciate the visual aspects of the spectroscopy and how to interpret these relative to the structure and chemistry of the sample. This is achieved by recognizing characteristic shapes and patterns within the spectrum, and by applying the information obtained from published group frequency data, along with other chemical and physical data from the sample.

Included in the text is a discussion of the interrelationships that exist between the practical side of acquiring the spectrum, the chemistry and physics of the sample under study, the physical interactions of the sample with its environment, and the impact of the structure on the spectrum. In essence, the interpretation of infrared spectra is much more than simply assigning group frequencies. The spectrum is rich in information, and this article is intended to help the reader to extract the maximum using the knowledge available for the sample and the acquired spectral data. One important factor to bear in

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

mind is that a successful interpretation is based not only on the *presence* of particular bands within the spectrum, but also the *absence* of other important bands. Complete classes of compounds can be rapidly excluded during the interpretation by the use of *no-band* information.

It must be understood that this article addresses the issue of infrared spectral interpretation from the perspective of the average operator of an infrared instrument. It is not a detailed treatise on the theory of infrared spectroscopy where the modes of vibration are discussed in terms of group theory, and where mathematical models are used to compare theoretical and observed values for the fundamental vibrations of a molecule. There are many excellent texts that cover this subject.[1–4] Instead, this article focuses on the day-to-day problems associated with characterizing a material or attempting to perform some form of identification. One of the main challenges in presenting a text on spectral interpretation is to form a balance between the theory that is needed to appreciate the links between molecular structure and the observed spectrum and the practice. For this reason, a minimum amount of relevant theory is included in the next section, which provides a basic understanding of why the spectrum exists, how it is formed, and what factors contribute to the complexity of observed spectra. It has been assumed that the reader has a fundamental knowledge of molecular theory and bonding, and that there is an understanding of basic structures, in particular for organic compounds.

Infrared spectral interpretation may be applied to both organic and inorganic compounds, and there are many specialized texts dealing with these compounds, in combination and as individual specialized texts. There are too many to reference comprehensively, and the reader is directed to a publication that provides a bibliography of the most important reference texts.[5] However, the most informative general reference texts are included,[6–14] with books by Socrates[10] and Lin-Vien[11] being recommended for general organics, and by Nakamoto[13] and Nyquist et al.[14] for inorganics (salts and coordination compounds). There are numerous specialized texts dealing with specific classes of materials, and undoubtedly polymers and plastics form the largest individual class.[15–17] In this particular case, texts by Hummel and Scholl[16] and Koenig[17] provide a good basic understanding.

The following comments are made relative to the conventions used within this article. The term frequency is used for band/peak position throughout, and this is expressed in the commonly used units of wavenumber (cm^{-1}). The average modern infrared instrument records spectra from an upper limit of around $4000\,cm^{-1}$ (by convention) down to $400\,cm^{-1}$ as defined by the optics of the instrument (commonly based on potassium bromide, KBr). For this reason, when a spectral region is quoted in the text, the higher value will be quoted first, consistent with the normal left-to-right (high to low cm^{-1}) representation of spectra. Also, the terms infrared band, peak and absorption will be used interchangeably within the text to refer to a characteristic spectral feature.

The spectral group frequencies provided in this text were obtained from various literature sources published over the past 30 years, and most of these are included in the cited literature. Every attempt to ensure accuracy has been taken; however, there will be instances when individual functional groups may fall outside the quoted ranges. This is to be expected for several reasons: the influences of other functional groups within a molecule, the impact of preferred spatial orientations, and environmental effects (chemical and physical interactions) on the molecule.

The preferred format for presenting spectral data for qualitative analysis is in the percentage transmittance format, which has a logarithmic relationship ($-\log_{10}$) with respect to the linear concentration format (absorbance). This format, which is the natural output of most instruments (after background ratio), provides the best dynamic range for both weak and intense bands. In this case, the peak maximum is actually represented as a minimum, and is the point of lowest transmittance for a particular band.

2 THE ORIGINS OF THE INFRARED SPECTRUM

In the most basic terms, the infrared spectrum is formed as a consequence of the absorption of electromagnetic radiation at frequencies that correlate to the vibration of specific sets of chemical bonds from within a molecule. First, it is important to reflect on the distribution of energy possessed by a molecule at any given moment, defined as the sum of the contributing energy terms (Equation 1):

$$E_{\text{total}} = E_{\text{electronic}} + E_{\text{vibrational}} + E_{\text{rotational}} + E_{\text{translational}} \quad (1)$$

The translational energy relates to the displacement of molecules in space as a function of the normal thermal motions of matter. Rotational energy, which gives rise to its own form of spectroscopy, is observed as the tumbling motion of a molecule, which is the result of the absorption of energy within the microwave region. The vibrational energy component is a higher energy term and corresponds to the absorption of energy by a molecule as the component atoms vibrate about the mean center of their chemical bonds. The electronic component is linked to the energy transitions of electrons as they

are distributed throughout the molecule, either localized within specific bonds, or delocalized over structures, such as an aromatic ring. In order to observe such electronic transitions, it is necessary to apply energy in the form of visible and ultraviolet radiation (Equation 2):

$$E = h\nu \qquad \text{frequency/energy} \tag{2}$$

The fundamental requirement for infrared activity, leading to absorption of infrared radiation, is that there must be a net change in dipole moment during the vibration for the molecule or the functional group under study. Another important form of vibrational spectroscopy is Raman spectroscopy, which is complementary to infrared spectroscopy. The selection rules for Raman spectroscopy are different to those for infrared spectroscopy, and in this case a net change in bond polarizability must be observed for a transition to be Raman active. The remaining theoretical discussion in this article will be limited to a very simple model for the infrared spectrum. The reader is encouraged to refer to more complete texts[2–4] for detailed discussion of the fundamentals.

While it was stated that the fundamental infrared absorption frequencies are not the only component to be evaluated in a spectral interpretation, they are the essence and foundation of the art. For the most part, the basic model of the simple harmonic oscillator and its modification to account for anharmonicity suffice to explain the origin of many of the characteristic frequencies that can be assigned to particular combinations of atoms within a molecule. From a simple statement of Hooke's law we can express the fundamental vibrational frequency of a molecular ensemble according to Equation (3):

$$\nu = \frac{1}{2\pi c}\sqrt{\frac{\kappa}{\mu}} \tag{3}$$

where ν = fundamental vibration frequency, κ = force constant, and μ = reduced mass. The reduced mass, $\mu = m_1 m_2/(m_1 + m_2)$, where m_1 and m_2 are the component masses for the chemical bond under consideration.

This simple equation provides a link between the strength (or springiness) of the covalent bond between two atoms (or molecular fragments), the mass of the interacting atoms (molecular fragments) and the frequency of vibration. Although simple in concept, there is a reasonably good fit between the bond stretching vibrations predicted and the values observed for the fundamentals.

This simple model does not account for repulsion and attraction of the electron cloud at the extremes of the vibration, and does not accommodate the concept of bond dissociation at high levels of absorbed energy. A model incorporating anharmonicity terms is commonly used to interpret the deviations from ideality and the overall energy–spatial relationship during the vibration of a bond between two atomic centers. The fundamental, which involves an energy transition between the ground state and the first vibrational quantum level, is essentially unaffected by the anharmonicity terms. However, transitions that extend beyond the first quantum level (to the second, third, fourth, etc.), which give rise to weaker absorptions, known as overtones, are influenced by anharmonicity, which must be taken into account when assessing the frequency of these higher frequency vibrations.

Having defined the basis for the simple vibration of an atomic bond, it is necessary to look at the molecule as a whole. It is very easy to imagine that there is an infinite number of vibrations, which in reality would lead to a totally disorganized model for interpretation. Instead, we describe the model in terms of a minimum set of fundamental vibrations, based on a threefold set of coordinate axes, which are known as the normal modes of vibration. All the possible variants of the vibrational motions of the molecule can be reduced to this minimum set by projection on to the threefold axes. It can be shown that the number of normal modes of vibration for a given molecule can be determined from Equations (4) and (5):

$$\text{number of normal modes} = 3N - 6 \text{ (nonlinear)} \tag{4}$$

$$= 3N - 5 \text{ (linear)} \tag{5}$$

where N is the number of component atoms in the molecule.

In practice, apart from the simplest of compounds, most molecules have nonlinear structures, except where a specific functional group or groups generate a predominant linear arrangement to the component atoms. If we calculate the number of modes for a simple hydrocarbon, such as methane (nonlinear, tetrahedral structure), a value of nine is obtained. This would imply that nine sets of absorption frequencies would be observed in the spectrum of methane gas. In reality, the number observed is far less, corresponding to the asymmetric and symmetric stretching and bending of the C–H bonds about the central carbon atom. The reason for the smaller than expected number is that several of the vibrations are redundant or degenerate, that is, the same amount of energy is required for these vibrations. Note that although a small number of vibrational modes is predicted, and in fact observed, the appearance of the methane spectrum at first glance is far more complex than expected, especially at higher spectral resolutions ($<1\,\text{cm}^{-1}$). At relatively high resolutions, a fine structure is superimposed, originating from rotational bands, which involve significantly lower energy transitions. Each of the sets of vibrational–rotational absorptions manifest this superimposed fine structure for low-molecular-weight gaseous compounds, methane being a good example. Several medium-molecular-weight

compounds may also show evidence of some fine structure when studied in the vapor state. For example, it is common to observe the sharp feature (or spike) assigned to the Q-branch of the vibrational–rotational spectrum, as indicated by the vapor spectrum of acetone (Figure 1).

If we proceed up the homologous series from methane (CH_4) to *n*-hexane (C_6H_{14}), there are 20 component atoms, which would imply 54 normal modes. In this case the picture is slightly more complex. Methane is a unique molecule, and only contains one type of C–H group – no other types of bond exist in this molecule. In hexane there are several types of bond and functionality. For reference, a simple two-dimensional representation of the structure is provided in Figure 2(a).

As we can see, there are two terminal methyl groups (CH_3) and four connecting methylene groups (CH_2). Each of these groups has its corresponding C–H stretching and bending vibrations (see later text for the actual absorption frequencies). Also, the methyl groups are linked to a neighboring methylene group, which is in turn linked to neighboring methylene groups, and so on. These linkages feature carbon–carbon bonds. For interpretation, we view the C–H groups as functional groups, giving rise to the common group frequencies, and the C–C linkages as the backbone, producing the skeletal vibrations. As a rule, a group frequency may be applied generally to most compounds featuring the corresponding functional group. In contrast, the skeletal vibrations are unique to a specific molecule. The group frequencies help to characterize a compound, and the

Figure 2 Structures for hexane isomers: (a) *n*-hexane and (b) isohexane (2-methylpentane). Copyright Coates Consulting.

combination of the bands associated with these group frequencies and the skeletal frequencies are used to identify a specific compound. The latter forms the basis of the use of reference spectra for spectral matching by visual comparison or by computer-based searching, for the identification of an unknown from its infrared spectrum.

The group frequencies may be viewed quantitatively, as well as qualitatively. A given absorption band assigned to a functional group increases proportionately with the number times that functional group occurs within the molecule. For example, in the spectrum of *n*-hexane, the intensities measured for the group frequency absorptions assigned to methyl and methylene correspond to four methylene groups and two methyl groups on a relative basis, when compared with other hydrocarbon compounds within a homologous series. For example, if we examine the C–H stretching (or bending) band intensities for CH_3 and CH_2, we will observe that the relative intensities of CH_3 to CH_2 decrease with increase in chain length. Restated, there is less methyl contribution and more methylene contribution with increase in chain length/molecular weight. The reverse holds true if we examine the spectra of linear hydrocarbons with chain lengths shorter than that of hexane.

If we apply these ideas to a different hexane isomer, such as isohexane (2-methylpentane), we would see significant differences in the spectrum. These can be explained by evaluating the structure (Figure 2b), which contains three methyl groups, two methylene groups, and a group that contains a single hydrogen attached to carbon (the methyne group). This adds a new complexity to the spectrum: the main absorptions show differences in appearance, caused by the changes in relative band intensities, splittings of absorptions occur (originating from spatial/mechanical interaction of adjacent methyl groups), and changes are observed in the distributions of the C–C skeletal vibrations, in part due to the splitting by the methyl side chain. Further discussions concerning the impact of chain branching are covered later in this article. Comparison of Figures 3 and 4 provides a graphical representation of the aspects discussed for the hexanes of structurally similar compounds, i.e. *n*-heptane and isooctane.

From a first-order perspective, the idea of the quantitative aspects of the group frequencies carries through for most functional groups, and the overall spectrum is essentially a composite of the group frequencies, with band intensities in part related to the contribution of each functional group in the molecule. This assumes that the functional group does give rise to infrared absorption frequencies (most do), and it is understood that each group has its own unique contribution based on its extinction coefficient (or infrared absorption cross-section).

Returning to the fundamental model, we should now look at the larger picture. In reality, we assign the

Figure 3 Attenuated total reflectance (ATR) spectrum of *n*-heptane. Copyright Coates Consulting.

Figure 4 ATR spectrum of 2,2,4-trimethylpentane (isooctane). Copyright Coates Consulting.

observed absorption frequencies in the infrared spectrum to much more that just simple harmonic (or anharmonic) stretching vibrations. In practice, we find that various other deformation motions (angular changes), such as bending and twisting about certain centers within a molecule, also have impact, and contribute to the overall absorption spectrum. By rationalizing the effort needed to move the atoms relative to each other, one can appreciate that it takes less energy to bend a bond than to stretch it. Consequently, we can readily accept the notion that the stretching absorptions of a vibrating chemical bond occur at higher frequencies (wavenumbers) than the corresponding bending or bond deformation vibrations, with the understanding, of course, that energy and frequency are proportionally related. A good example is the C–H set of vibrations, observed in the hydrocarbon spectra, and in virtually all organic compounds. Here, the simple C–H stretching vibrations for saturated aliphatic species occur between 3000 and 2800 cm^{-1}, and the corresponding simple bending vibrations nominally occur between 1500 and 1300 cm^{-1}.

Next in our understanding is that it can take slightly more energy to excite a molecule to an asymmetric than a symmetric vibration. While this might be less intuitive, it is still a rational concept, and therefore easy to understand and accept. Again, we see a good example with the C–H stretch of an aliphatic compound (or fragment), where we observe the asymmetric C–H stretch of the methyl and methylene groups (2960 and 2930 cm^{-1}, respectively) occurring at slightly higher frequency than symmetric vibrations (2875 and 2855 cm^{-1}, respectively for methyl and methylene). For the most part, this simple rule holds true for most common sets of vibrations. Naturally there are always exceptions, and a breakdown of the rationale may occur when other effects come into play, such as induced electronic, spatial or entropy-related effects.

There are many other spatially related scenarios that tend to follow well-orchestrated patterns, examples being in-plane and out-of-plane vibrations, the differences between *cis* and *trans* spatial relationships, and a variety of multicentered vibrations that are defined as twisting or rocking modes. Many of these are exhibited with the C–H vibrations that occur in saturated, unsaturated and aromatic compounds. Molecular symmetry of the static or the dynamic (during vibration) molecule has a large impact on the spectrum, in addition to factors such as relative electronegativity, bond order and relative mass of the participating atoms.

Finally, while discussing the vibrational origins of infrared spectra, it is worth commenting that further complexity may be noted in the spectrum, beyond what is expected based on the fundamentals. As noted, transitions to higher energy levels, although theoretically not allowed, can occur and these give rise to overtone bands, which in the mid-infrared region occur at approximately twice the fundamental frequency for the first overtone. Higher overtones exist, typically the second (3 × fundamental) and third (4 × fundamental), and sometimes higher, and these are observed, with extremely low intensity, relative to the fundamental in the near-infrared spectral regions, between 800 and 2500 nm (12 500 and 4000 cm^{-1}). Other types of bands that can add complexity to a spectrum are combination bands (sum and difference), bands due to transitions from energy states higher than the ground state or ''hot bands'', and bands due to interactions between a weaker overtone or combination band and a fundamental of the same or similar frequency, known as Fermi resonance bands. In the latter case, two relatively strong absorptions are observed, where normally only a single absorption is expected for the fundamental.[3]

As additional functional groups are added to a basic backbone structure, forming a more complex molecule, additional bands are observed, either directly associated with the fundamental vibrations of the functional groups, or indirectly related to interactions between component

functional groups or the basic substructure. Such interactions can be severe, and result in overwhelming distortions in the appearance of the spectrum, a good example being hydrogen bonding. This will be dealt with in depth later.

3 SPECTRAL INTERPRETATION BY APPLICATION OF VIBRATIONAL GROUP FREQUENCIES

This section includes tabulated data relative to the most significant group frequencies for the most common functional groups and structural components found in organic compounds. Brief reference is also made to simple inorganic compounds, in the form of simple ionic species. More detailed listings can be found in published literature, and the reader is encouraged to acquire one or more of these reference texts.[9–13] As already indicated, the use of tabulated data is only a part of the interpretation process, and other facets of the spectrum must be taken into account.

To help gain an understanding of infrared spectral interpretation, it is instructive to start at the root of most organic compounds, namely the fundamental backbone or the parent hydrocarbon structure. We shall start with the simple, aliphatic hydrocarbon, which is at the root of most aliphatic compounds. Aliphatic hydrocarbons exist in simple linear chains, branched chains and in cyclic structures – examples of the linear and branched chain scenarios were provided earlier for hexane isomers. Any one molecule may exist with one or more of these component structures. The infrared spectrum can provide information on the existence of most of these structures, either directly or by inference.

The introduction of unsaturation in the form of a double or triple bond has a profound impact on the chemistry of the molecule, and likewise it has a significant influence on the infrared spectrum. Similarly, the same is observed when an aromatic structure is present within a molecule. Infrared spectroscopy is a powerful tool for identifying the presence of these functionalities. It provides information specific to the group itself, and also on the interaction of the group with other parts of the molecule and on the spatial properties of the group. Examples of these include conjugation between a double bond and another unsaturated center, an aromatic ring or a group, such as a carbonyl (C=O), and the orientation or location of the double bond within the molecule, such as *cis* or *trans* and medial or terminal. It should be noted that *cis*/*trans* relationships are not specific to unsaturated hydrocarbons, and the terminology is referenced elsewhere, such as with secondary amide structures. Again, the associated changes in the spatial arrangement of the groups involved is reflected in the infrared spectrum as additional bands and added complexity.

As we move on to simple organic compounds, where one or more functional groups or heteroatoms are added to the molecule, we see many changes occurring in the spectrum. These result from the bonding associated with the functional group, and also local disturbances to the basic backbone spectrum that relate again to spatial changes and also to local and neighboring electronic effects. Examples of such functionalities are halogens, simple oxygen species, such as hydroxy and ether groups, and amino compounds. Carbonyl compounds, where the added functional group includes the C=O bond, also provide very profound contributions to the spectrum, and because of the wide diversity of these compounds they are best dealt with as a separate class.

A very characteristic group of compounds, from a spectral point of view, are the multiple-bonded nitrogen compounds, such as cyanides and cyanates. These typically have very characteristic absorptions, which are easy to assign, and are free from spectral interferences. The same can be said for some of the hydrides of heteroatoms, such as sulfides (thiols), silanes, and phosphines. Finally, there are other, oxygen-containing functional groups, as encountered in the nitrogen-oxy (NO_x), phosphorus-oxy (PO_x), silicon-oxy (SiO_x), and sulfur-oxy (SO_x) compounds. These are sometimes more difficult to identify from first principles, and a knowledge of the presence of the heteroatom is helpful. The spectra are characteristic, but many of the oxy absorptions occur within a crowded and highly overlapped region of the spectrum, mainly between 1350 and 950 cm^{-1}. Also, many of these compounds feature C–O bonding, which is common in other frequently encountered functionalities such as ethers and esters.

3.1 The Hydrocarbon Species and Molecular Backbone

In this section we include the characteristic absorption frequencies encountered for the parent hydrocarbon species and the associated backbone or substituent group. This includes aliphatic and aromatic structures. The spectral contributions are characterized, as previously noted, as C–H stretching and bending vibrations and C–C vibrations (stretching and bending), which for the most part are unique for each molecule, and are generally described as skeletal vibrations. In the case of aromatic compounds, ring C=C–C stretching and bending vibrations are highly characteristic, and are diagnostic. Likewise, the same can be said for the unsaturated carbon–carbon multiple bonding in alkene and alkyne structures.

Table 1 Saturated aliphatic (alkane/alkyl) group frequencies

Group frequency (cm^{-1})	Functional group/assignment
	Methyl ($-CH_3$)
2970–2950/2880–2860	Methyl C–H asym./sym. stretch
1470–1430/1380–1370	Methyl C–H asym./sym. bend
1385–1380/1370–1365	*gem*-Dimethyl or "iso"- (doublet)
1395–1385/1365	Trimethyl or "*tert*-butyl" (multiplet)
	Methylene ($>CH_2$)
2935–2915/2865–2845	Methylene C–H asym./sym. stretch
1485–1445	Methylene C–H bend
750–720	Methylene $-(CH_2)_n-$ rocking ($n \geq 3$)
1055–1000/1005–925	Cyclohexane ring vibrations
	Methyne ($>CH-$)
2900–2880	Methyne C–H stretch
1350–1330	Methyne C–H bend
1300–700	Skeletal C–C vibrations
	Special methyl ($-CH_3$) frequencies
2850–2815	Methoxy, methyl ether O–CH_3, C–H stretch
2820–2780	Methylamino, N–CH_3, C–H stretch

3.1.1 Saturated Aliphatic and Alicyclic Compounds

See Table 1. The C–H stretch vibrations for methyl and methylene are the most characteristic in terms of recognizing the compound as an organic compound containing at least one aliphatic fragment or center. The bending vibrations help to tell more about the basic structure. For example, a strong methylene/methyl band ($1470\,cm^{-1}$) and a weak methyl band ($1380\,cm^{-1}$), plus a band at $725–720\,cm^{-1}$ (methylene rocking vibration) is indicative of a long-chain linear aliphatic structure (note that splitting may be observed for the 1470 and $720\,cm^{-1}$ bands, which is indicative of a long-chain compound, and is attributed to a crystallinity and a high degree of regularity for the linear backbone structure). In contrast, strong methyl bands, showing significant splitting, and a comparatively weaker methylene/methyl band indicate chain branching, and the possibility of isopropyl or *tert*-butyl substituents (depending on the amount of splitting, and the relative band intensities). A comparison between linear and branched chain hydrocarbons can be seen in Figures 3 and 4, where in the case of isooctane, both isopropyl and *tert*-butyl groups are present.

3.1.2 Unsaturated Compounds

See Table 2. As already commented upon, the saturated hydrocarbon C–H stretching absorptions all occur below $3000\,cm^{-1}$. Any band structures observed between 3150 and $3000\,cm^{-1}$ are almost exclusively indicative of unsaturation (C=C–H) and/or aromatic rings. The

Table 2 Olefinic (alkene) group frequencies

Origin	Group frequency, wavenumber (cm^{-1})	Assignment
C=C	1680–1620	Alkenyl C=C stretch
	1625	Aryl-substituted C=C
	1600	Conjugated C=C
C–H	3095–3075 +3040–3010	Terminal (vinyl) C–H stretch
	3095–3075	Pendant (vinylidene) C–H stretch
	3040–3010	Medial, *cis*- or *trans*-C–H stretch
C–H	1420–1410	Vinyl C–H in-plane bend
	1310–1290	Vinylidene C–H in-plane bend
C–H	995–985 + 915–890	Vinyl C–H out-of-plane bend
	895–885	Vinylidene C–H out-of-plane bend
C–H	970–960	*trans*-C–H out-of-plane bend
	700 (broad)	*cis*-C–H out-of-plane bend

Figure 5 ATR spectrum of 1-hexene. Copyright Coates Consulting.

unsaturated hydrocarbons featuring C=C, with attached hydrogens, usually occur as either a single or a pair of absorptions, in the ranges indicated in Table 2. As noted, the number of bands and their positions are indicative of the double bond location and the spatial arrangement around the double bond. The position of the C=C stretching frequency does vary slightly as a function of orientation around the double bond, but it is less informative than the C–H information. The C–H out-of-plane bending is typically the most informative relative to the location and spatial geometry of the double bond, where terminal and medial double bonds may be clearly differentiated. Figure 5 provides a good example with the spectrum of 1-hexene, which contains the terminal vinyl group. Note that a fully substituted, medial double bond has only the C=C as the sole indicator of the presence of the double bond, unless the bond is conjugated with a second unsaturated site.

Table 3 Aromatic ring (aryl) group frequencies

Origin	Group frequency, wavenumber (cm^{-1})	Assignment
C=C–C[a]	1615–1580	Aromatic ring stretch
C=C–C[a]	1510–1450	Aromatic ring stretch
C–H	3130–3070	Aromatic C–H stretch
C–H	1225–950 (several)	Aromatic C–H in-plane bend
C–H	900–670 (several)	Aromatic C–H out-of-plane bend
	770–730 + 710–690	Monosubstitution (phenyl)
	770–735	1,2-Disubstitution (ortho)
	810–750 + 900–860	1,3-Disubstitution (meta)
	860–800	1,4-Disubstitution (para)
"Combi"[b]	2000–1660 (several)	Aromatic combination bands

[a] C=C–C used as an approximation of the unique aromatic ring bonding.
[b] "Combi" denotes assignment to combination bands.

3.1.3 Aromatic Compounds

See Table 3. The existence of one or more aromatic rings in a structure is normally readily determined from the C–H and C=C–C ring-related vibrations. The C–H stretching occurs above 3000 cm^{-1} and is typically exhibited as a multiplicity of weak-to-moderate bands, compared with the aliphatic C–H stretch. The structure of the bands is defined by the number and positions of the C–H bonds around the ring, which in turn are related to the nature and number of other substituents on the ring. Note that the same applies to the C–H out-of-plane bending vibrations, which are frequently used to determine the degree and nature of substitution on the ring – examples are provided in Figure 6(a–c), with the comparison of the three xylene isomers. This picture often becomes more complex if multiple- or fused-ring structures exist in a compound. The other most important set of bands are the aromatic ring vibrations centered around 1600 and 1500 cm^{-1}, which usually appear as a pair of band structures, often with some splitting. The appearance and ratio of these band structures is strongly dependent on the position and nature of substituents on the ring.

3.1.4 Acetylenic Compounds

See Table 4. Although acetylenic compounds are not very common, the spectrum associated with the C≡C structure can be characteristic. It is instructive to note the impact on the carbon–carbon bond stretching as a function of increase in bond order for the series of single-, double-, and triple-bonded carbon:

C–C stretch: ~1350–1000 cm^{-1} (skeletal vibrations)
C=C stretch: 1680–1620 cm^{-1}
C≡C stretch: 2260–2100 cm^{-1}

Figure 6 ATR spectra of xylene isomers: (a) *o*-xylene, 1,2-dimethylbenzene; (b) *m*-xylene, 1,3-dimethylbenzene; (c) *p*-xylene, 1,4-dimethylbenzene. Copyright Coates Consulting.

Table 4 Acetylenic (alkyne) group frequencies

Origin	Group frequency, wavenumber (cm^{-1})	Assignment
C≡C	2140–2100	Terminal alkyne (monosubstituted)
C≡C	2260–2190	Medial alkyne (disubstituted)
C–H	3320–3310	Alkyne C–H stretch
C–H	680–610	Alkyne C–H bend
C–H	630 (typical)	Alkyne C–H bend

This increase in bond order produces a corresponding increase in bond strength, which in turn increases the force

constant, κ (see Equation 3), supporting the Hooke's law model described earlier.

As noted in Table 4, the position of the C≡C bond is influenced by whether the group is terminal or medial. The single hydrogen of the terminal acetylene itself is very characteristic, reflecting the labile nature of the acetylenic C–H.

3.2 Simple Functional Groups

Obviously, there is a potentially broad number of molecular fragments that can be considered to be functional groups attached to an organic structure or backbone. This section features the most simple and most common of the functional groups, –C–X, i.e. the halogens (X = F, Cl, Br and I), hydroxy (X = OH), oxy or ether (X = OR, where R = alkyl), and amino ($X = NH_2$, =NH or ≡N). With the exception of the carbonyl functionality, these three basic functional groups cover most of the common occurrences in simple organic compounds. Note that for the oxy/hydroxy and amino functionalities, these are molecular fragments, and they contribute their own set of characteristic absorptions to the spectrum of the compound. In fact, the bonding between the functional group and the backbone is only one part of the overall picture used for the spectral interpretation.

3.2.1 Halogenated Compounds

See Table 5. In principle, the interpretation of the spectra of molecules containing one or more halogens would seem to be straightforward. The functionality is simple, with just a single atom linked to carbon to form the group. With the polar nature of this group, one would expect the spectral contribution to be distinctive. In reality, this is not always the case.

In aliphatic compounds, the C–X bond typically possesses a unique group frequency, which may be assigned to the halogen–carbon stretching. When a single halogen is present, the determination of this group is straightforward. However, if more than one halogen is present, the interpretation is usually more complex. In such cases, the result varies depending on whether the halogens are on the same or different carbon atoms, and, if on different atoms, whether the atoms are close neighbors. This is particularly the case with small molecules, and the resultant spectral complexity arises from the fact that there is restricted rotation about the carbon–carbon bond.

Single bonds usually exhibit free rotation, which would normally mean that there are no preferred spatial orientations for the molecules. However, owing to the size of the halogen atom, relative to the carbon and hydrogen that form the backbone, the molecules tend to exhibit certain specific conformations, where the spatial interaction between neighboring halogen atoms is minimized, and each conformation provides its own contribution to the overall spectrum. It is important to appreciate that this issue of spatial orientation has an impact even on high-molecular-weight compounds, such as the polyhalogenated polymers, e.g. poly(vinyl chloride). Here preferred orientations have an impact on the crystallinity of the polymer, and this in turn has a significant impact on both the spectrum and the physical properties of the material.

Another important issue to consider with halogen substituents is the high electronegativity of the halogen atom. This can have a noticeable impact on the spectrum of neighboring group frequencies, including adjacent hydrogen atoms. In such cases, significant shifting of the C–H frequencies can occur – the direction of the shift being dependent on the location of the C–H, and whether the halogen adds or extracts electron density from the C–H bond – adding strengthens (higher frequency) and extracting weakens (lower frequency). The same influences can be observed with halogen-substituted carbonyl compounds, such as acyl halides and α-substituted acids, where the bond strength of the carbonyl group is increased (see section 3.3). In most cases, both a shift to higher frequency and an increase in absorption strength for the band are observed.

Table 5 only presents the group frequencies for the aliphatic compounds, because no well-defined C–X absorptions are observed for halogen-substituted aromatic compounds. The presence of a halogen on an aromatic ring can be detected indirectly from its electronic impact on the in-plane C–H bending vibrations. Normally, we do not consider the in-plane bending bands to be of use because, as pointed out earlier, these occur in a spectral region that is crowded by other important group frequencies. However, in the case of a halogen-substituted ring, the intensity of these vibrations is enhanced relative

Table 5 Aliphatic organohalogen compound group frequencies

Origin	Group frequency, wavenumber (cm^{-1})[a]	Assignment
C–F	1150–1000	Aliphatic fluoro compounds, C–F stretch
C–Cl	800–700	Aliphatic chloro compounds, C–Cl stretch
C–Br	700–600	Aliphatic bromo compounds, C–Br stretch
C–I	600–500	Aliphatic iodo compounds, C–I stretch

[a] Note that the ranges quoted serve as a guide only; the actual ranges are influenced by carbon chain length, the actual number of halogen substituents, and the molecular conformations present.

to other absorptions by as much as three to four times. For reference, it is informative to compare the intensities for these bands, between 1150 and 1000 cm^{-1}, for the spectra of toluene and chlorobenzene (Figure 7a and b).

3.2.2 Hydroxy and Ether Compounds

See Table 6 for alcohols and hydroxy compounds. The hydroxy function is probably one of the most dominant and characteristic of all of the infrared group frequencies. In most chemical environments, the hydroxy group does not exist in isolation, and a high degree of association is experienced as a result of extensive hydrogen bonding with other hydroxy groups. These hydroxy groups may be within the same molecule (intramolecular hydrogen bonding) or they most likely exist between neighboring molecules (intermolecular hydrogen bonding). The impact of hydrogen bonding is to produce significant band broadening and to lower the mean absorption frequency. The lowering of the frequency tends to be a function of the degree and strength of the hydrogen bonding. In compounds such as carboxylic acids, which exhibit extremely strong hydrogen bonding, forming a stable dimeric structure, a highly characteristic, large shift to lower frequencies is observed.

Table 6 Alcohol and hydroxy compound group frequencies

Origin	Group frequency, wavenumber (cm^{-1})	Assignment
O–H	3570–3200 (broad)	Hydroxy group, H-bonded OH stretch
	3400–3200	Normal "polymeric" OH stretch
	3550–3450	Dimeric OH stretch
	3570–3540	Internally bonded OH stretch
O–H	3645–3600 (narrow)	Nonbonded hydroxy group, OH stretch
	3645–3630	Primary alcohol, OH stretch
	3635–3620	Secondary alcohol, OH stretch
	3620–3540	Tertiary alcohol, OH stretch
	3640–3530[a]	Phenols, OH stretch
O–H	1350–1260	Primary or secondary, OH in-plane bend
	1410–1310	Phenol or tertiary alcohol, OH bend
	720–590	Alcohol, OH out-of-plane bend
C–O	~1050[b]	Primary alcohol, C–O stretch
	~1100[b]	Secondary alcohol, C–O stretch
	~1150[b]	Tertiary alcohol, C–O stretch
	~1200[b]	Phenol, C–O stretch

[a] Frequency influenced by nature and position of other ring substituents.
[b] Approximate center of range for the group frequency.

In special circumstances, where the hydroxy group is isolated – either because of steric hindrance effects or because the sample is in the vapor state or in a dilute solution of a nonpolar solvent – the band is characteristically narrow, and is observed at the natural, higher frequency. This absorption is important for the characterization of certain hindered phenol antioxidants, a commercially important class of compounds in the food, polymer, and formulated oil industries.

It must be appreciated that while the hydroxy absorption is singly one of the most important bands in the infrared spectrum, other vibrations are also important for the actual characterization of the compound. Alcohols exist as three distinct classes – primary, secondary and tertiary – distinguished by the degree of carbon substitution on the central hydroxy-substituted carbon, a single substitution being primary, double substitution being secondary, and triple substitution being tertiary. This is an important fact, because the chemistry and oxidation stability of the alcohol are strongly influenced by the degree of substitution. Whether an alcohol is primary (1°), secondary (2°) or tertiary (3°), may be reflected in the position of the OH stretch absorption, but typically this is determined by the other absorptions, in particular the C–O– stretching frequency. Another absorption of lower importance, but often characteristic, is assigned

to another form of bending vibration, the out-of-plane bend or wagging vibration of the O–H. The OH bending vibrations are broadened by hydrogen bonding as is the stretching absorption, but often to a lesser extent. The differences between primary and secondary alcohols can be appreciated from Figure 8(a) and (b), where the spectra of 1- and 2-octanol are presented.

See Table 7 for ethers and oxy compounds. In some respects, ethers are related to alcohol and hydroxy compounds, where the hydrogen of the hydroxy group is replaced by an aliphatic (alkyl) or aromatic (aryl) molecular fragment. Having stated that, the overall appearance of an ether spectrum is drastically different from that of a related alcohol. This is due to the overwhelming effect of hydrogen bonding on the hydroxy group. However, many of the relationships that exist for the C–O component of the alcohol carry over to the corresponding ether. The relationships that pertain to primary, secondary, and tertiary structures remain intact. The main difference is that one now considers the bonding on both sides of the oxygen, because if carbon is on both sides, then two ether bonds exist. Ethers can exist as simple ethers (same group both sides) and mixed ethers (different groups both sides). Infrared spectroscopy is fairly sensitive for differentiating these ether functions, especially when the structures are mixed aliphatic or aliphatic/aromatic.

Table 7 Ether and oxy compound group frequencies

Origin	Group frequency, wavenumber (cm^{-1})	Assignment
C–H	2820–2810	Methoxy, C–H stretch (CH_3–O–)
C–O–C	1150–1050	Alkyl-substituted ether, C–O stretch
C–O–C	1140–1070	Cyclic ethers, large rings, C–O stretch
ϕ–O–H	1270–1230	Aromatic ethers, aryl–O stretch
C–O–	~1250 + 890–800[a]	Epoxy and oxirane rings
C–O–O–C	890–820[a]	Peroxides, C–O–O– stretch

[a] Typically very weak, and not very characteristic in the infrared. Tend to be more characteristic in the Raman spectrum.

3.2.3 Amino Compounds

See Table 8. In some respects, the infrared spectra and the characteristic group frequencies of amines tend to

Table 8 Amine and amino compound group frequencies

Origin	Group frequency, wavenumber (cm^{-1})	Assignment
		Primary amino
N–H	3400–3380 +3345–3325	Aliphatic primary amine, NH stretch
N–H	3510–3460 +3415–3380	Aromatic primary amine, NH stretch
N–H	1650–1590	Primary amine, NH bend
C–N	1090–1020	Primary amine, CN stretch
		Secondary amino
>N–H	3360–3310	Aliphatic secondary amine, NH stretch
>N–H	~3450	Aromatic secondary amine, NH stretch
>N–H	3490–3430	Heterocyclic amine, NH stretch
=N–H	3350–3320	Imino compounds, NH stretch
>N–H	1650–1550	Secondary amine, NH bend
C–N	1190–1130	Secondary amine, CN stretch
		Tertiary amino
C–N	1210–1150	Tertiary amine, CN stretch
		Aromatic amino
C–N	1340–1250	Aromatic primary amine, CN stretch
C–N	1350–1280	Aromatic secondary amine, CN stretch
C–N	1360–1310	Aromatic tertiary amine, CN stretch

parallel those of alcohols and ethers. Before proceeding, there is an important distinction to be made between the nomenclature used to describe alcohol structures, compared with that used for amines. The terms primary, secondary, and tertiary are used to describe amines, but the substitution relates to the nitrogen, not the adjoining carbon (as with alcohols). The terminology used is $-NH_2$ primary, >NH secondary and >N– tertiary. As before, these structural differences are important, and they strongly influence the chemistry and the reactivity of the nitrogen and the N–H group (primary and secondary). Again, the infrared spectrum is very diagnostic, and it is possible to differentiate readily the functional group structures, especially for the primary and secondary amino compounds (see Figure 9a–c for an example comparison of primary, secondary, and tertiary aromatic amines).

As with hydroxy compounds, hydrogen bonding is important, but the effect tends to be weaker than for the hydroxy group, and the overall effect on the spectrum is slightly less pronounced. This situation alters in the related ammonium and amino salts, where strong hydrogen bonding is experienced, and a corresponding broadening of the associated NH absorptions is observed.

Note that only the primary and secondary amines exhibit the most characteristic group frequencies, which are associated with the N–H bond. Tertiary amines are very comparable to ethers, and the main diagnostic information is gathered from the C–N vibrations only. An important exception is the methylamino (and dimethylamino) group, which like its counterpart (methoxy in ethers) has a characteristic C–H stretching vibration at lower than the normal C–H stretching frequency for methyl.

3.3 The Carbonyl Group

Carbonyl compounds are not only chemically important, but are also important in the interpretation of infrared spectra. The C=O absorption is almost always one of the most characteristic in the entire spectrum, and it is also most likely to be the most intense spectral feature. Table 9 provides an example listing of some of the common carbonyl frequencies as a function of the particular type of carbonyl group. In essence, a ketone is considered the root compound, with an aldehyde being a special case, where the carbonyl group is terminal, and only has one substituent, the other being a single hydrogen atom. All of the other carbonyl compounds, in a way, can be considered to be derived from the base ketone structure, where one or both alkyl (or aryl) substituents are replaced by another functionality, e.g. from a single hydroxy group, in the case of carboxylic acids, to two ether groups, as in the case of an organic carbonate.

Figure 9 ATR spectra of (a) primary (aniline), (b) secondary (*N*-methylaniline) and (c) tertiary (*N*,*N*-dimethylaniline) aromatic amines. Copyright Coates Consulting.

The actual diagnostic carbonyl absorption frequency is dependent on the electronic characteristics of the substituent group, which in turn define very much the chemical characteristics and reactivity of the specific carbonyl compound. Spatial and structural factors can be important, in particular ring stress, as in the case of lactones (cyclic esters) and lactams (cyclic amides). In this case, the greater the ring stress, the higher is the carbonyl absorption frequency. In common with previous observations for a double-bonded functionality, conjugation plays an important role in the observed carbonyl frequency. This includes connection to an aromatic ring or conjugation to a C=C or another C=O.

Table 9 Example carbonyl compound group frequencies

Group frequency (cm^{-1})	Functional group
1610–1550/1420–1300	Carboxylate (carboxylic acid salt)
1680–1630	Amide
1690–1675/(1650–1600)[a]	Quinone or conjugated ketone
1725–1700	Carboxylic acid
1725–1705	Ketone
1740–1725/(2800–2700)[b]	Aldehyde
1750–1725	Ester
1735	Six-membered ring lactone
1760–1740	Alkyl carbonate
1815–1770	Acid (acyl) halide
1820–1775	Aryl carbonate
1850–1800/1790–1740	Open-chain acid anhydride
1870–1820/1800–1775	Five-membered ring anhydride
2100–1800	Transition metal carbonyls

[a] Lower frequency band is from the conjugated double bond.
[b] Higher frequency band characteristic of aldehydes, associated with the terminal aldehydic C–H stretch.

As previously discussed, a lowering of the parent group frequency is observed. This effect is important for the differentiation of certain types of carbonyl compound, in the determination of whether the carbonyl group is directly or indirectly attached an aromatic ring, e.g. the ability to differentiate aryl acetates from alkyl benzoates. In the case of the acetate, the ring is joined to the ''ether oxygen'' of the ester group, and is not conjugated with the carbonyl, whereas with the benzoate, the ring is directly conjugated with the group, and the carbonyl absorption frequency is correspondingly lowered.

Often, the frequency ranges for the different classes of carbonyl compound overlap, and the carbonyl frequency alone is not sufficient to characterize the functional group. In most cases, spectral information from the other component of the functional group is used for the characterization. Carboxylic acids are a good example, where the C–O, C–O–H and O–H vibrations are highly characteristic. Similarly, esters (C–O–C) and amides (C–N and N–H) are other frequently encountered examples. The frequencies provided earlier for these additional functionalities (C–O, C–N, and N–H) in general apply, although the actual observed frequencies may differ slightly, being modified by the carbonyl group. It is worthwhile returning momentarily to carboxylic acids, because they are unique, in so far as the hydroxy group has direct interaction with the carbonyl group, by the formation of a stable dimeric hydrogen-bonded structure in the condensed phase (solid and liquid). Note that this structure disappears in the vapor state. A characteristic broad feature in the range 3300–2500 cm^{-1}, that overlaps the C–H stretching region, and with a secondary absorption close to 2600 cm^{-1}, is observed for the hydrogen-bonded O–H of most carboxylic acids. The impact of this overlap can be appreciated by reference to the spectrum of butyric acid, provided in Figure 10. Other bands that are associated with the C–O and O–H components tend to be less pronounced, and sometimes may be overlapped with other fingerprint absorptions of the molecule. These are located in the ranges 1320–1210 cm^{-1} (C–O stretch) and 960–850 cm^{-1} (hydrogen-bonded O–H out-of-plane bending).

3.4 Other Functional Groups Associated with Heteroatoms

Potentially there are very large numbers of different organic-based compounds that are associated with one or more heteroatoms. These are in addition to the simple halogen- and amino-based compounds that have already been covered. A detailed discussion of such compounds is beyond the scope of this article. A few illustrative examples are included here in order to provide the reader with a feel for the spectral contributions of commonly encountered compounds that feature heteroatoms. These include triple-bonded and cumulated double-bonded nitrogen compounds, such as cyano and cyanato compounds, hetero-oxy compounds, such as nitro, sulfoxy, phosphoroxy and silicoxy compounds, and thiols and thio-substituted compounds. Many of these belong to important compound classes, and complete texts exist that focus on the spectral attributes of such compounds.

3.4.1 Multiple-bonded and Cumulated Double-bonded Nitrogen Compounds

Nitrogen compounds featuring triple or cumulated double bonds, such as cyanides or nitriles (–C≡N) and cyanates (–O–C≡N), all provide a unique spectrum, typically with a single, normally intense absorption at 2280–2200 cm^{-1}

Figure 10 Transmission spectrum of *n*-butyric acid. Copyright Coates Consulting.

(for cyano compounds) and 2285–1990 cm^{-1} (cyanates, isocyanates, thiocyanates, etc.). The band is assigned to the stretching vibration, which is the asymmetric stretch in the case of the cumulated double-bonded compounds (the symmetric stretch is typically weak, and is not diagnostic of the group).

Double-bonded nitrogen groups, such as imino groups (>C=N–) and azo groups (–N=N–), exhibit absorptions close to the carbonyl (C=O) and alkene (C=C) double bond stretching region. While they are characteristic for the functional group, they are sometimes difficult to assign from first principles because of the overlap with other common functional groups in the region. For example, dependent on substitution or location, the >C=N– group can occur in the same spectral region as the C=O of an amide. Examples of the group frequencies for a few common multiple-bonded and cumulated double-bonded compounds are provided in Table 10.

3.4.2 Hetero-oxy Compounds

The group of compounds covered here feature X–O (where X = nitrogen, sulfur, phosphorus, and silicon) and X=O vibrations. In general, the characteristic absorptions span a similar range to that covered by the corresponding carbon–oxygen compounds, with most of the stretching frequencies observed within the main fingerprint spectral region (1500–400 cm^{-1}). Many of the compounds can be considered to be analogs of ethers, especially when an alkoxy group is present, featuring the X–O–C linkage. Interestingly, the nitro group ($-NO_2$) is isoelectronic with the carboxylate ion group ($-CO_2^-$), and both provide very similar spectra for the main functional group. See Table 11 for example group frequencies for hetero-oxy compounds.

3.4.3 Thiols and Thio-substituted Compounds

Thiols and thio-substituted compounds, by definition, can be considered to be the direct analogs of the equivalent oxygenated compounds such as alcohols and ethers. Unlike the oxygen-containing analogs, the equivalent C–S and C–S–H stretching vibrations tend to give rise to very weak absorptions in the infrared spectrum. The C–S and S–H bonds are highly polarizable, and hence produce stronger spectral activity in the Raman spectrum than the infrared spectrum. The higher mass of sulfur, compared with oxygen, results in the characteristic group frequencies occurring at noticeably lower frequencies than the oxygen-containing analogs, as noted in Table 12 for compounds containing S–H and C–S bonds. The thiol S–H is probably the only infrared absorption that can be considered to be of use for the general characterization of these compounds, and most of the others are obtained by inference, or from knowledge of the compound type. Catenation is a unique chemical characteristic of sulfur, where the formation of S–S bonds in extended chains is common, hence the inclusion here of the S–S stretching frequencies.

Table 10 Examples of nitrogen multiple and cumulated double bond compound group frequencies

Group frequency (cm^{-1})	Functional group/assignment
2280–2240	Aliphatic cyanide/nitrile
2240–2220	Aromatic cyanide/nitrile
2260–2240/1190–1080	Cyanate (–OCN and C–OCN stretch)
2276–2240	Isocyanate (–N=C=O asym. stretch)
2175–2140	Thiocyanate (–SCN)
2150–1990	Isothiocyanate (–NCS)
1690–1590	Open-chain imino (–C=N–)
1630–1575	Open-chain azo (–N=N–)

Table 11 Example group frequencies for simple hetero-oxy compounds

Group frequency (cm^{-1})	Functional group/assignment
	Nitrogen-oxy compounds
1560–1540/1380–1350[a]	Aliphatic nitro compounds

3.5 Simple Inorganics

Characterization of compounds via infrared spectroscopy is not limited to organic compounds. Any inorganic compound that forms bonds of a covalent nature within a molecular ion fragment, cation or anion, will produce a characteristic absorption spectrum, with associated group frequencies. In a manner, certain aspects

Table 12 Common group frequencies for thiols and thio-substituted compounds

Group frequency (cm^{-1})	Functional group/assignment
2600–2550	Thiols (S–H stretch)
710–685	Thiol or thioether, CH_2–S– (C–S stretch)
660–630	Thioethers, CH_3–S– (C–S stretch)
715–670	Aryl thioethers, ϕ–S (C–S stretch)
705–570	Disulfides (C–S stretch)
620–600	Disulfides (S–S stretch)
500–430	Aryl disulfides (S–S stretch)
500–470	Polysulfides (S–S stretch)

Table 13 Example group frequencies for common inorganic ions

Group frequency (cm^{-1})	Functional group/assignment
1490–1410/880–860[a]	Carbonate ion
1130–1080/680–610[a]	Sulfate ion
1380–1350/840–815[a]	Nitrate ion
1100–1000	Phosphate ion
1100–900	Silicate ion
3300–3030/1430–1390[a]	Ammonium ion
2200–2000	Cyanide ion, thiocyanate ion, and related ions

[a] Typically, the first absorption is intense and broad, and the second has weak to medium intensity and is narrow. Both often exist as multiple band structures, and this may be used to characterize individual compounds.

have already been covered for inorganic compounds in the form of salts of carboxylic acids and amino and ammonium compounds, which can be extended to metal complexes, chemical fragments associated with hetero-oxy groups (nitrates, sulfates, phosphates, silicates, etc.), and transition metal carbonyl compounds. All complex ionic compounds (containing more than one atom) and coordination compounds produce characteristic spectra. Many of the associated group frequencies can be used diagnostically for characterization. The structure and orientation of the ion or complex, both as an isolated entity or within a crystal lattice, are important factors that affect the appearance and nature of the infrared spectrum. Hydration of compounds (water of crystallization) also has a large effect on the spectrum, and often adds a lot of complexity, in the form of additional absorption bands and structure to existing bands. The subject is far too broad to be covered in this article, and only a few example group frequencies are included here (Table 13). The reader is directed to the recommended standard texts for more detailed information.[13,14]

4 THE PRACTICAL SITUATION – OBTAINING THE SPECTRUM AND INTERPRETING THE RESULTS

Up to this point, the fundamentals of interpretation have been discussed from the most basic concepts of infrared absorption by a molecular species and the impact of chemical functionality on the resultant spectrum. In many ways, this discussion has treated the molecule as a more or less isolated species, with no consideration of the physical state of the actual sample or the environment in which the molecule exists. Physical state and the molecular, chemical and physical environments have a profound effect on the infrared spectrum. As a result, it is just as important to understand and interpret these effects as it is to perform the fundamental interpretation of the functional groups from first principles.

This particular section may be one of the most important for many of the readers, because it reflects the real world, that is taking a sample, preparing it for analysis, and making use of all of the available information on the sample and the spectrum or spectra obtained. Note that sometimes there are several options in the way that a sample may be handled for infrared analysis. It is often beneficial to consider the different options. Before we start to examine the situation it is important to understand the importance of the interpretation and to determine the real requirements. Here are some example scenarios:

1. The sample (or spectrum) is a ''total unknown'' and an identification is required – examples include forensic samples, environmental waste samples, or new discovery samples, where a new material has been synthesized or discovered.
2. The sample (or spectrum) is an unknown and it needs to be characterized or classified – examples include commercial applications where new additives or components are included in a material to provide a specific property; in such cases this could be considered the basis of competitive product analysis.
3. The sample generally is known but the existence of a specific chemical class needs to be determined – examples include contaminant analysis, analysis for toxicology or environmental reasons, material additives, etc.
4. The sample is a complete known and the interpretation is required to confirm the material composition and/or quality – examples include product quality control and the confirmation of a structure or functionality of a newly synthesized material.

There are clearly many other scenarios that can be considered, and the examples presented may cross over into more than one of these scenarios. However, the idea here is to help define a strategy for the interpretation. For the most part, this text will focus on scenarios 1 and 2, although a passing reference may be made to the others. Note also that there are two ways to address the interpretation:

- one is to attempt to assign as many bands as possible using group frequency tables;
- the other is to attempt to build up a picture using information from key spectral bands (with a knowledge of the group frequencies) and rationalizing the spectrum relative to the sample as known, and any known history, including the sample preparation and presentation technique.

The latter approach is the best way to go, and is typically far more rewarding. Also, it is seldom that all bands in the infrared spectrum of a sample can be fully or accurately assigned. There are too many ambiguities and coincidences for a definitive interpretation to be obtained from the spectra of most materials – remembering, of course, that the sample may be a mixture.

To begin, let us start from either the point where a spectrum has been generated or where a sample is presented. In practice, these are very different starting points. The latter is always preferred because with the sample in hand it is possible to gain a lot of first-hand information about nature which will ultimately help in the final interpretation. The term ''unknown'' is used because this is how people often view the interpretation process; however, in reality there are seldom true unknowns – in other words, the reason for the interpretation itself often provides implied information about the sample. Even if a person presents a prerecorded spectrum, it is usually accompanied by some additional information. This at minimum should include a knowledge of how the sample was prepared, whether it is a solid, liquid, or gas, or some mixed state, and maybe some physical characteristics (color, appearance, melting point/boiling point, etc.). For the benefit of presenting a complete picture, we shall assume that the sample is available and that we have the opportunity to perform additional tests and measurements on it. Further, more detailed discussions of this practical approach can be found in the literature.[18–20]

4.1 Sample History

As noted, we are seldom dealing with a true unknown, and typical situations include the following:

- a sample of fiber taken or extracted from a particular environment;
- a contaminant removed from a material;
- a suspicious liquid found leaking out of some drums;
- a residue extracted from a surface;
- a residual liquid or solid remaining after storage or treatment of a product;
- extracted additives or components from a commercial product;
- a mass that was produced after a specific chemical reaction;
- or simply a manufactured product.

Most people can equate with these different sets of circumstances. Each one brings information about the sample.

In the case of a fiber, if it is organic, then it typically fits within certain classes of polymeric materials. It may have orientation properties, which will influence the appearance of the infrared spectrum, depending on how it is sampled, and if there is more than one fiber, then the original material may have been a blend. The environment from where the sample was taken will be important because there may be surface contaminants that may produce spurious bands in the spectrum, which may be removed by some sample pretreatment, such as washing with a solvent. Alternatively, the fiber may be coated, or degraded, thermally or by oxidation.

The characterization of contaminants is a common application for infrared spectroscopy. For this type of exercise it is necessary to know the importance of the contaminant and why it is believed to be a contaminant. Was it extracted from a liquid or solid matrix? if so, what type of matrix, and what was the composition of the matrix? Is it possible that the contaminant originated from the matrix itself, as a breakdown product? – if so, then there should be some chemical similarities or common heritage. Was it embedded within a matrix, such as a plastic/polymer film or a sheet of paper? – if so, is the contaminant itself potentially contaminated by the matrix? This is especially important for interpretation, because the matrix may have a very intense infrared spectrum of its own.

For extracted materials, such as additives removed from a polymer, it is important to know something about the polymer matrix – few extractions are 100% efficient, and it is common to have carry-over. In many such cases, the spectrum obtained reflects that of a mixture rather than a pure compound. Things to bear in mind here are what the original base polymers were, what other additives could be present, and what material, usually a solvent, was used for the extraction.

Looking at residues and residual products of a reaction is similar to the concept of characterizing a contaminant. Residues formed within products are often the result of a breakdown reaction or an unexpected interaction between components. If derived from one or more of the components, then a knowledge of all of the ingredients is essential – again we would be looking for chemically related species in the residue, and reference spectra of each of the ingredients would be important in attempting to characterize the material. In the case of a reaction product, spectra for the reactants and any solvents or substrates (catalysts, etc.) used would be helpful.

Finally, the identification of an end product from its infrared spectrum is common practice. By definition, unless the final product is a pure chemical, most manufactured products are mixtures, often featuring blended solid and/or liquid components from percentage range concentrations to trace amounts. Often at issue is how much can be identified from the interpretation of a single spectrum. It is often necessary to perform some form of preconcentration on one or more ingredients, or to perform a chemical modification to change the spectral response of one or more of the major ingredients. This latter operation may help to remove the spectral interferences from a major component for determining the presence of minor components.

4.2 Physical Characteristics of the Sample

From considerations based on the discussions in the section above, a good working knowledge of the sample allows one to determine basic information about the sample. This information can help in the determination of the best method of sampling. It can also help to indicate if any special treatments to the sample are necessary before proceeding, such as the removal of residual solvents, or the need for selective extraction, in the event that the sample has more than one phase, or is known to be a mixture. Beyond this there are other important physical characteristics of the sample that can assist the interpretation process. As indicated, physical state can be very important. For example, it has been noted that nitro compounds are isoelectronic with organic acid salts. Many simple nitro compounds are liquids, whereas simple carboxylates are usually solids.

There are, however, many other physical characteristics and attributes that can be linked to the sample and its chemistry. This in turn can be linked to important spectral features in the infrared spectrum. Two important characteristics are color and odor. Nitrogen compounds often have color associated with them, e.g. nitro-substituted compounds often have a characteristic yellow or orange color, especially substituted phenols and amines. Similarly, unsaturated nitrogen compounds, such as azo compounds, and highly conjugated olefinic compounds, such as carotenes, are similarly colored. This can be used as a guide to look for the specific functionality in the spectrum.

Likewise, odor can be a useful guide. This author is not advocating that a person should inhale the vapor of a sample directly, for obvious reasons. However, if under cautious sampling conditions a characteristic odor is detected, then this can provide a valuable insight regarding the presence of particular functional groups. Common examples are alcohols, esters, and ketones, which often possess relatively pleasant fragrances, especially when associated with some degree of unsaturation. An almond-like odor might indicate a nitro compound, benzaldehyde, or a cyano compound (caution!), a fish-like odor is often associated with amino or amido compounds, and a putrid or ''bad-cheese'' odor is associated with certain carboxylic acids. With time, one can build up a mental library of common odors and fragrances, and these can be very valuable for initial material screening, by helping one look for the presence of specific functional groups.

Volatility and flammability can be useful guides. Most volatile compounds tend to have a relatively low molecular weight, and they usually are unassociated. This latter point helps to rule out certain hydrogen-bonded species, such as carboxylic acids, amines, and multiple hydroxy-substituted compounds (such as glycols). If a sample is submitted for some form of combustion analysis, it is worthwhile monitoring how it burns. If it burns with a clean, bluish flame, that might indicate that the sample is oxygenated (alcohol or ether). If it has a yellow and/or smoky flame, it indicates an excess of carbon, possible unsaturation or an aromatic compound. The latter can produce a very smoky flame.

4.3 The Chemistry of the Sample

First, there are issues relating to solubility. The old adage, like dissolves like, is very appropriate. Nonpolar materials such as hydrocarbons tend to be more soluble in nonpolar solvents, such as hydrocarbons or chlorinated solvents, whereas polar materials favor solvents such as methanol and acetone, and in extreme cases their solubility may be limited to the most polar solvents, such as water. If a material is potentially identified from its infrared spectrum as a carboxylic acid or an amino compound, then it is worthwhile to check the pH. Also, it is worthwhile to check its ability to form a salt – carboxylic acids react with sodium carbonate or sodium hydroxide to form a carboxylate salt, and amines react with dilute mineral acids, such as hydrochloric acid, to form amine salts (amine hydrochlorides with hydrochloric acid).

Certain compounds react with water; examples are acid halides and acid anhydrides. Alternatively, these

compounds will react with alcohols and amines to form esters and amides. The formation of such derivatives is common practice in the identification of organic compounds, and can be extremely informative in a definitive identification by infrared spectroscopy. Other chemical modifications that can be equally informative are for the identification of olefinic or unsaturated compounds. A simple reaction with bromine (caution – use in solution, or prepare in situ) will often confirm the presence of a double bond. The reaction product can be helpful in characterizing the nature of the unsaturation, especially in the case of a *cis* configuration, which is often spectrally masked by other absorptions in the region.

One similar modification, which is strictly not chemical in nature, is deuterium exchange. In this case, a compound with either a labile hydroxy group or an amino group is placed in equilibrium with a deuterated solvent, such as deuterium oxide (heavy water). The replacement of the O–H in the molecule by O–D, in the case of hydroxy compounds, can help in the confirmation of the hydroxy group, and it can shift an overlapping hydroxy function from the C–H stretching and bending regions, thereby assisting in the determination of the backbone structure. Note that the shift induced by the replacement of O–H by O–D is nearly as much as $1000\,cm^{-1}$.

Finally, an important chemical characteristic to be understood is hydrogen bonding. The infrared spectrum is a wonderful tool for helping to monitor the presence of this phenomenon. However, one must be aware of the fact that hydrogen bonding is usually concentration dependent. If a hydroxy compound is examined in a nonpolar solvent, one should be aware that the hydroxy group spectrum, in particular bands assigned to the stretching vibration, will change shape, position, and intensity as a function of concentration. Also, diagnostically, if the hydroxy group bands do not change significantly with concentration, then this is a strong indication of intramolecular (internal) hydrogen bonding. This latter information is important in helping to determine the spatial relationships of hydroxy groups within a molecule.

The last two sections might seem to be obvious basic knowledge in the chemistry and physical properties of a material. However, just simple observations of the type described can be invaluable in determining the presence of specific functional groups when used in combination with the infrared spectrum. Likewise, the use of negative spectral information, viz. the absence of a characteristic group frequency, is equally important. For example, if a sample has an almond-like odor, but does not have a strong band between 2200 and $2000\,cm^{-1}$, then the compound is more likely to be a nitro compound or benzaldehyde than a cyano compound. If an aldehydic carbonyl group is absent, then the compound probably contains a nitro group.

4.4 The Infrared Sampling Method

The final appearance of the infrared spectrum is very important in the interpretation process. Where possible, it always helps to be able to study the sample as it occurs naturally, without any form of physical modification. This eliminates the possibility of any interactions, or even chemical modifications. A common method for handling solid samples is known as the compressed alkali metal halide pellet method (KBr pellet or disk method). This method of sample preparation is prone to difficulties, and it often requires a skilled operator to produce good-quality spectra on a routine basis. A poor sampling technique with this method can lead to spectral artifacts and distortions, all of which can cause difficulties in the interpretation. Furthermore, some compounds may react with KBr, causing either a liberation of the halogen (oxidants) or halogen exchange (halide salts). The act of applying pressure can also change the appearance of the spectrum, especially when a material exists in more than one polymorphic form. The pressure may cause one polymorph to dominate, thereby changing the entire absorption band distribution of the spectrum. This is especially a problem with certain pharmaceutical products.

Other pretreatment methods, such as melts and cast films for solid samples, can cause similar problems. The cooling process (from melts) or the casting process can induce preferential crystallization of a particular form of the material, and sometimes preferred orientations can result. All of these effects can give rise to nonrepresentative spectra, which can cause interpretation problems.

With liquids, it is always beneficial to examine the sample as it is received. Liquid transmission cells have been used successfully in the past, but care and attention must be paid to the nature of the window material and to the cell pathlength. Low-molecular-weight materials usually require very short pathlengths in order to obtain a good-quality spectrum with most of the absorption bands on-scale. If too many bands bottom out, it is difficult to ascertain the relative intensity of certain key functional groups, and sometimes key factors, such as band splitting, may be missed. Also, if the sample is of low molecular weight, and volatile, it is important to ensure that the cell seals adequately.

In recent years, focus has been placed on reflectance methods of measurement, primarily from the surface of a sample. The most common methods are diffuse reflectance, specular reflectance and/or transflectance, and ATR. Generally, these are nondestructive methods, and require only a minimum amount of sample

preparation. The specular and transflectance methods have found greatest use with microscope-based methods of spectral measurement. Diffuse reflectance and ATR are important laboratory methods, and both lend themselves to rapid and reproducible sampling. However, both methods have an impact on the spectrum, and neither method necessarily provides a true spectrum of the sample free from some form of distortion or aberration. ATR is the simplest to handle, and its main limitation is that it provides a spectrum where the spectrum intensity across the spectrum increases as a function of wavelength. Both diffuse reflectance and specular reflectance can be the most difficult to handle, because both methods can cause severe band distortions, linked to surface and refractive index phenomena. In all three cases, the nature and the origin of the distortions are understood, and can be assigned to known physical properties. If necessary, software algorithms can be applied to correct for most of the distortions – a wavelength correction function in the case of ATR (for qualitative use), and a spectrum transformation, known as the Kramers–Kronig transform, in the case of surface reflectance distortions.

One other technique that is not so common but is important for certain ''difficult-to-handle'' samples is photoacoustic spectroscopy. The accessory, which also functions as the detector, provides a true absorption spectrum from a sample directly, with no sample modification. It is particularly good for samples that naturally have high absorption, such as carbon-filled materials, and for materials that are a good thermal conductor. As with ATR spectra, there is a wavelength dependence of the peak intensity across the spectrum.

The entire subject of sample handling is very broad, and generally falls outside the scope of this article. However, its impact on the final infrared spectrum and its resultant impact on the interpretation process can be very profound. Therefore, the reader is encouraged to read specific texts that address the subject in greater detail.[21–23]

5 AN OVERVIEW TO INFRARED SPECTRAL INTERPRETATION – SOME SIMPLE RULES AND GUIDELINES

This final section is a review of the ideas presented so far as to how to go about the interpretation of an infrared spectrum. With it, there is the implied understanding that the infrared spectrum is only one source of information, and additional information is most likely required for a satisfactory analysis of the spectrum. The following are a set of simple guidelines to help a person through the early stages of rationalizing an infrared spectrum and to get to the first stages of an interpretation. However, note that this is not a definitive set of rules.

First, it is important to appreciate that there are often recurring patterns in the spectrum that are characteristic of certain classes or compounds and/or functional groups. Such patterns can be far more diagnostic in the interpretation process than merely isolated group frequencies. Examples include the overall appearance of the hydrogen-bonded hydroxy functionality, the patterns associated with unsaturation and aromaticity, and the combinations of bands used to characterize different carbonyl compounds. To start, it is worthwhile to determine if the compound is organic (evidence of C–H functionality) and if there is a characteristic chain or ring associated with the compound. Having determined this, it is worthwhile to reflect on the complexity of the spectrum, and to see if one or two characteristic functionalities, associated with simple functional groups (–OH, –NH, C=O, etc.) are present. Often, the like-to-like rule applies – that is, a simple spectrum is usually indicative of a simple molecular structure, and vice versa.

If the spectrum clearly indicates multiple functionality, then be aware that mutual interaction may be occurring, and this may be causing some deviations from ideality, relative to the common group frequency assignments. Also, remember that multiple functionality might reflect a complex structure, but it might also reflect that the sample is a mixture. In both cases, an appreciation of the existence of spectral coincidences is very important. For example, a strong absorption between 1250 and 1150 cm^{-1} can be assigned to numerous types of chemical bonds, from the C–F group to the Si–O group. A careful assessment of the other spectral features, and most likely an understanding of the nature of the sample, will usually help in resolving some of these spectral coincidence situations. The use of known relative band intensities for certain functional groups can also be helpful in determining whether band overlap is occurring, and in particular whether the bands from a group are being obscured by other more intense bands. A good example is the overlap of the *cis* C–H out-of-plane bending vibration, which is typically overlapped by the $-(CH_2)_n-$ rocking vibration of long-chain aliphatic compounds.

Also, if multiple functionality exists, some form of separation scheme may be in order to help determine if the sample is a mixture and, if so, to help separate some of the components. While this may not always be necessary – there are many commercial mixtures identifiable from the original spectrum – it is often required for a more definitive evaluation of a sample from its infrared spectrum. An example of such a mixture is provided in Figure 11. The spectrum of this four-component mixture can be interpreted from a knowledge of the components – acetone, methanol, dichloromethane

Figure 11 ATR spectrum of a commercial solvent mixture containing methanol, dichloromethane, toluene and acetone. Copyright Coates Consulting.

and toluene. However, the use of separation techniques, such as water-based solvent extraction, and partial distillation can help in determining the identity of the components.

Finally, in terms of using the first-assessment rules outlined in the remainder of this section, it is important to incorporate all known chemical and physical information, including pertinent test data, such as the presence of unsaturation, which may be used to corroborate the spectral data for a suspected double bond. Remember that simple information, such as color and odor, can be equally important – highly conjugated compounds and nitro compounds often give rise to significant color, and numerous functional groups, such as esters, ketones, unsaturation, and nitro groups, have highly characteristic fragrances or odors, even in the solid state.

The following first assessment guide is based on the examination of critical spectral regions for evidence of highly characteristic molecular backbones or fragments and functional groups. An important point to remember here is that negative information, in the form of no-band regions, is extremely important, and helps to eliminate major classes of chemical compounds, thereby reducing the number of possibilities in the final interpretation.

5.1 A Quick Diagnostic Assessment of an Infrared Spectrum

5.1.1 Step 1: Overall Spectrum Appearance

Is the spectrum simple? Are there only a few main characteristic absorption bands, say less than five?

If the spectrum is simple, as defined, then the compound may be a low-molecular-weight organic or inorganic compound, such as a simple salt of a common molecular ion (carbonate, sulfate, nitrate, ammonium, etc.) or a covalent species (chloroform, dichloromethane, methanol, water, etc.). In this case, the physical properties are important – if the material is a crystalline solid, then it is most likely a salt; if it is a mobile, possibly volatile, liquid, then the latter probably applies. Note that there are always exceptions, e.g. bromoform and iodoform, simple covalent compounds, are crystalline solids (both melt at low temperatures, whereas salts do not). One other class of compounds worth mentioning here is simple polymers, such as polyethylene and polytetrafluoroethylene, both of which exhibit very simple spectra when obtained from thin films.

Are some of the bands broad? Hydrogen bonding possibly exists and can be exhibited in hydrates, water solutions, alcohols, ammonium compounds, amino compounds, etc. Note that some inorganics may exhibit a combination of both broad and very narrow bands, even for certain hydrated species. These are often related to the crystalline structure of the compound and the symmetry of certain aspects of the molecular/ionic structure.

5.1.2 Diagnostic Step 2: Testing for Organics and Hydrocarbons – Absorptions in the Region 3200–2700 cm^{-1}

Well-defined and characteristic absorptions in this region are normally characteristic of carbon- and hydrogen-containing species, and are assigned to various forms of C–H stretching.

Are there absorptions above 3000 cm^{-1}? If yes, then the compound is likely to be unsaturated (contains C=C) or aromatic. If isolated absorptions occur at 3010 and/or 3040 cm^{-1}, then the absorbing species is mostly simple olefinic unsaturation.

Is the main absorption below 3000 cm^{-1}? If so, the compound is probably aliphatic. If the main absorptions are approximately 2935 and 2860 cm^{-1}, and there are also absorptions at 1470 and 720 cm^{-1}, then the compound probably contains a long linear aliphatic chain.

5.1.3 Diagnostic Step 3: Testing for Hydroxy or Amino Groups – Absorptions in the Region 3650–3250 cm^{-1}

Hydroxy or amino groups mainly dominate this region, both giving rise to very characteristic band profiles. The presence or absence of hydrogen bonding is well delineated in this region. One other characteristic vibration that is observed in this region, which is unlikely to be confused with any other functional group, is the C–H stretch of a terminal alkyne (acetylenic compound). This exhibits a relatively narrow absorption at

3300 cm^{-1}, and is associated with a second (C≡C) band at 2200 cm^{-1}.

Is the main absorption band in the area broad? If so, the compound is probably a hydroxy or amino group. Knowledge of the presence of nitrogen or a nitrogenous base (pH or titration) helps to support an amino compound.

Are there additional moderate to intense bands in the ranges 1600–1300, 1200–1000 and 800–600 cm^{-1}? If so, the compound is likely to be a simple hydroxy compound. Remember that the simple hydrogen-bonded OH absorption of a hydroxy (alcohol) function has a very characteristic shape.

If the feature is relatively sharp and occurs between 3670 and 3550 cm^{-1}, the compound probably contains a non-hydrogen-bonded hydroxy group, often an alcohol or phenol with a sterically hindered OH group. Note also that this spectral feature is also exhibited by certain inorganics and minerals, and is indicative of a ''free'' OH group, either on the surface, or embedded within a crystal lattice, and free from interactions with other ions or groups.

5.1.4 Diagnostic Step 4: Testing for Carbonyl Compounds – Absorptions in the Region 1850–1650 cm^{-1}

A major band in this region usually indicates the presence of a C=O group (carbonyl compound). Note that certain C=N (imino) and N=N (azo) groups may interfere, example compounds being purines.

Is the absorption at the high end of the range, e.g. 1775 cm^{-1} or above? If yes, the compound probably contains a reactive carbonyl, such as an anhydride, acid halide (acyl halide) or α-halogenated carbonyl, or a strained-ring carbonyl, such as a lactone, or an organic carbonate.

Is the absorption in the middle of the range, 1750–1700 cm^{-1}? If yes, the compound is probably a simple carbonyl compound, such as a ketone, an aldehyde, an ester, or a carboxylic acid.

Is the absorption at the low end of the range, e.g. below 1700 cm^{-1}? If yes, the compound is probably an amide or a carboxylate (carboxylic acid salt). Note that conjugation with another carbonyl group, or a double bond or aromatic ring, will lower the carbonyl absorption by 30–50 cm^{-1}. Therefore, conjugated aldehydes, ketones, esters, and carboxylic acids may fall into this lower end category. If conjugation with a double bond is present, then a second strong absorption should be observed nearby, between 1650 and 1600 cm^{-1}. In the case of the involvement of an aromatic ring, it is important to look for evidence of the characteristic aromatic absorptions (see Diagnostic Step 6).

5.1.5 Diagnostic Step 5: Testing for Unsaturation – Weak to Moderate Absorption in the Region 1670–1620 cm^{-1}

Note that this is not a particularly definitive diagnostic without the support of other corroborating absorptions.

A relatively narrow, weak-to-moderate absorption, normally centered around 1650 cm^{-1}, is indicative of olefinic unsaturation (C=C). A lowering of this frequency, accompanied by intensification of the band, is characteristic of conjugation with another double bond structure, such as C=C, C=O or an aromatic ring (see comments in Diagnostic Step 4).

The test for unsaturation normally involves a check for C–H peaks above 3000 cm^{-1}, and typically as a single, or possibly a pair, of absorptions (dependent on configuration of the double bond) at ~3085 cm^{-1} and/or ~3025 cm^{-1} – not to be confused with the multiple band situation for aromatics (see Diagnostic Step 6).

Are there single or multiple bands between 1000 and 880 cm^{-1} (C–H out-of-plane bending)? If so, this, in combination with the 1650 and 3010 and/or 3040 cm^{-1} bands, can be used as an assignment of unsaturation. This is either terminal (or vinyl $-CH=CH_2$), with a pair of bands, normally located about 990 cm^{-1} and close to 900 cm^{-1}, or trans unsaturation (CH=CH), with a band centered around 965–960 cm^{-1}. A single band around 890 cm^{-1}, in conjunction with the other unsaturation absorptions, can indicate a vinylidene (or pendant, $C=CH_2$) type of olefinic double bond.

Note that a *cis* configuration (CH=CH) is sometimes hard to characterize, because the normally characteristic C–H out-of-plane bending is broad, with only a moderate absorption, and occurs in a region (around 700 cm^{-1}) where it can overlap with absorptions from other structural components, such as long-chain aliphatics, aromatics, and halogen compounds.

5.1.6 Diagnostic Step 6: Testing for Aromatics – Well-defined Absorptions in the Region 1615–1495 cm^{-1}

One, but typically two, sets of bands in the region, with one set around 1600 cm^{-1} and the other around 1500 cm^{-1}, are consistent with an aromatic compound. Sometimes the absorptions occur as single bands, at other times one or more of the band sets may appear split, as an asymmetric doublet. This assignment is usually confirmed by the presence of other bands in the spectrum.

Are there a series of weak-to-moderate absorptions in the region 3150–3000 cm^{-1}, which can be assigned to aromatic C–H stretching? These usually support the presence of the 1600/1500 cm^{-1} aromatic ring bands (see Diagnostic Step 2).

For simple aromatic compounds, a series of weak absorptions may be observed between 2000 and 1700 cm^{-1}. These are multiple combination bands that are noticeably weak, and are typically not to be confused with an isolated weak carbonyl absorption.

The C–H bending vibrations can also be used to support the presence of an aromatic structure. If there are medium-to-strong absorptions, sometimes more than one, between 850 and 670 cm^{-1}, these can be assigned to C–H out-of-plane bending on an aromatic ring. These support the assignment of the 1600/1500 cm^{-1} bands, and the locations of the bands are often indicative of the nature of the substitution of the aromatic ring. For simple structures, it is possible to differentiate mono-, di- (ortho, meta and para), and certain poly-substitutions. Note that a single, strong band may support simple ortho (around 750 cm^{-1}) or para (around 830 cm^{-1}) substitution.

Many organic compounds have multiple band structures in the region 1150–950 cm^{-1}. The in-plane C–H bending vibrations of aromatic compounds typically occur in this region, and can exist as complex band structures (multiple, well-defined bands). They tend not to be diagnostic for many compounds because of conflict and overlap with other functional group absorptions, including some skeletal (backbone) vibrations. However, they are clearly observable in simple hydrocarbons as weak-to-moderate absorptions, and in halogen-substituted aromatic compounds (such as chlorobenzenes) as characteristic strong absorptions.

5.1.7 Diagnostic Step 7: Testing for Multiple Bonding (Often with a Bond Order of 2 or Higher) – Absorption in the Region 2300–1990 cm^{-1}

Multiply bonded nitrogen compounds and cumulated multiple bond compounds, such as cyanides (nitriles), cyanates, isocyanates, thiocyanates, and diazo compounds, exhibit characteristic absorptions in the region 2300–1990 cm^{-1}. Cyanide absorptions vary from weak to moderate to strong, depending on the nature of other substituents in the molecule. Conjugation, including substitution on an aromatic ring, modifies the intensity of this absorption.

If the absorption band is extremely strong, the group is more likely to be a three-center functionality, such as a cyanate, an isocyanate, or a thiocyanate.

Acetylenes and alkyne substituents also exhibit a weak-to-moderate absorption within the same spectral region. If the acetylenic function is internal (medial), then the absorption can be extremely weak. However, a terminal alkyne group (C≡C) band may have moderate intensity, and this is supported by a characteristic C–H stretching absorption around 3310 cm^{-1}. A relatively low-frequency C–H bending vibration around 630 cm^{-1} also confirms the terminal alkyne vibration.

Metal carbonyls have unique bonding, where the bond order between the carbon and oxygen is between two and three, and where the additional electrons are provided by dπ back-bonding from the accompanying transition metal atom. The multiply bonded CO group provides an extremely intense absorption band close to 2000 cm^{-1} (typically between 2100 and 1900 cm^{-1}), the actual position of the band(s) and the complexity of the bands being dependent on the structure of the compound.

Note that an isolated weak-to-moderate intensity absorption above the specified region, and typically between 2700 and 2400 cm^{-1}, is not normally associated with a multiply bonded compound. These absorptions are usually from hydride vibrations, such as from silanes (Si–H), thiols and sulfides (S–H), phosphines (P–H), arsines (As–H), boranes (B–H), etc. Knowledge of the existence of the accompanying heteroatom helps in the assignment of the X–H bonds in these compounds.

This concludes the summary data for a first-pass assessment of an infrared spectrum, based on the most common and characteristic group frequencies. The technique is not foolproof, but for many simple compounds, if one systematically applies the diagnostic tests on the spectrum from a sample, as presented above, it is possible to gain some understanding of the chemical functionality. It is always hoped that more information can be gained from the sample, either by first-hand knowledge or by asking questions, or by performing additional tests. Once a basic interpretation is accomplished, and the sample is broadly characterized, it is recommended that reference spectra are used to try to obtain a more exact match to the sample. Always bear in mind that the sample could be a mixture, such as a commercially formulated/compounded material. In such cases, an exact match may not be possible, unless the reference spectrum exists for the formulation.

Analytical techniques that combine liquid chromatography (LC) and infrared (IR) spectroscopy have been developed primarily to permit specific detection and/or identification of sample constituents. LC is an important and extensively used method for the separation of mixtures into their individual components. IR spectroscopy is very useful for the characterization of functional groups and has strong compound-identification capabilities which are especially suited for the differentiation of structural isomers. Over the past years the coupling of LC and IR spectroscopy (LC/IR) has been accomplished by two different approaches. The first and simplest approach is to use a flow cell through which the effluent from the LC column is passed while the IR spectra are continuously measured. The merits of flow-cell IR detection include ease of operation, real-time detection and low maintenance, but its main disadvantage lies in the significant IR-absorption of the solvents commonly used in LC. These absorptions seriously limit both the detection sensitivity and the obtainable spectral information. The second approach involves elimination of the LC solvent prior to IR detection. In this approach an interface is used to evaporate the eluent and deposit the separated compounds onto a substrate suitable for IR detection. The primary advantages of solvent-elimination LC/IR are the possibility to obtain full spectra of the analytes and the considerably enhanced sensitivity when compared to flow-cell detection. Unfortunately, common LC solvents, and particularly aqueous eluents, are not easily removed and therefore the evaporation interfaces are often rather complex. This article reviews the developments, practical aspects, applications and current status of LC/IR, covering both coupling approaches. It follows that despite the unfavorable detection limits, flow-cell LC/IR can be useful for the specific and quantitative detection of major components of mixtures. However, solvent-elimination-based IR-detection should be used when small amounts of sample constituents have to be characterized with a high level of confidence. In general, the practical use of IR detection in LC is still limited, but the advent of various (commercial) flow-cell and interface designs shows that LC/IR is more and more being recognized as a feasible and rewarding technique.

1 INTRODUCTION

IR spectroscopy has a high potential for the elucidation of molecular structures. The IR spectrum of a polyatomic molecule is based on molecular vibrations, each specifically dependent on atomic masses, bond strengths and intra- and intermolecular interactions. As a consequence, the entire IR spectrum of an organic compound provides a unique fingerprint, which can be readily distinguished from the IR-absorption patterns of other compounds including isomers. In other words, when reference spectra are available, most compounds can be unambiguously identified on the basis of their IR spectra. Moreover, characteristic absorption bands can be used for compound-specific detection.

LC is a powerful and versatile separation technique, which can handle a wide range of sample types and compound classes. Because of the widespread use of LC and the (growing) need for analytical procedures that provide confirmation and/or identification of sample constituents, much effort has been – and still is – devoted to the coupling of LC with spectrometric techniques such as mass spectrometry (MS), IR and nuclear magnetic

resonance (NMR) spectroscopy. Today, with modern Fourier transform infrared (FTIR) instrumentation routinely available, spectra can be recorded from nanogram, or even picogram, amounts of pure substance so that IR detection, in principle, is suited for molecular recognition at analyte levels frequently met in LC. Unfortunately, because of the (spectral) characteristics of the mobile phase, the coupling of LC and IR spectroscopy (LC/IR) is not straightforward and often requires the construction of special flow cells or the development of rather complex interfaces. Therefore, compared with other LC detection modes such as ultraviolet/visible (UV/VIS) absorption spectroscopy or MS, the use of IR detection in LC is still rather limited. Nevertheless, progress in interfacing techniques during the last decade has brought LC/IR to a stage of analytical utility which suggests that LC/IR may well become a commonly available and applied technique.

2 COUPLING MODES AND OPERATING PRINCIPLES

In the first LC/IR systems[1,2] flow cells were used in a fashion analogous to LC with on-line UV/VIS absorption detection. In order to circumvent interfacing difficulties related to the IR absorptions of the mobile phase, in 1979 Kuehl and Griffiths[3] developed the first solvent-elimination based LC/IR set-up in which the eluent is evaporated prior to IR detection. Since then two approaches can be discerned in LC/IR, namely, the flow-cell approach and the solvent-elimination approach. In the contemporary practice of LC/IR both approaches are applied, although the detection limits and spectral information obtained with either approach may differ considerably. The principles, applications, merits and limitations of flow-cell and solvent-elimination LC/IR have been reviewed in a number of books and papers.[4–8]

2.1 Flow-cell Approach

The simplest way to couple LC and IR is to let the column effluent pass directly through a flow cell suited for IR measurements. The IR absorption of the LC effluent is continuously monitored and spectral data are collected on-the-fly and stored throughout the chromatographic run. During or after the run, the spectra and/or IR chromatograms are computed and absorption due to the mobile phase is subtracted. In a flow-cell design, band broadening caused by detection is easily minimized.

Unfortunately, the absolute sensitivity of IR spectroscopy is relatively poor compared to spectrometric techniques like MS, UV/VIS and fluorescence spectroscopy. Moreover, solvents suited for LC generally have many absorption bands in the IR region, which leads to serious limitations of flow cell LC/IR interfacing. Firstly, absorption bands of analytes may be obscured by eluent absorptions. In other words, in flow-cell LC/IR, the spectral information that can be obtained is limited and depends on the window provided by the mobile phase used. Moreover, ill-considered subtraction of solvent absorption bands may lead to the erroneous conclusion that there is no absorption of the analyte in the corresponding spectral regions. Secondly, gradient elution can hardly be applied as the changing composition of the mobile phase frustrates proper subtraction of the background. To some extent, the second derivative of a spectrum can be used to compensate for this problem, but accurate spectral correction is virtually impossible. Thirdly, the pathlength of the flow cell has to be limited to ensure a certain spectral window and sufficient energy reaching the IR detector. For organic solvents commonly used in LC/IR, the effective pathlength rarely exceeds 1 mm which, bearing in mind Beer's law, seriously reduces the analyte detectability. For aqueous eluents, the largest tolerable pathlength is even shorter. As can be seen from the spectrum of water in Figure 1, most of the mid-IR region between 4000 and 1000 cm^{-1} is opaque, even at a very short pathlength of 10 μm. It implies that a practical combination of reversed-phase liquid chromatography (RPLC) and IR via a transmission flow cell is restricted to specific applications. Finally, the use of signal averaging to improve the signal-to-noise ratio (S/N) of the spectra is limited owing to the short time that is available for analysis under dynamic conditions. Occasionally, the principle of stop-flow can be used to enhance the S/N without too much loss in chromatographic performance.

The choice for a certain mobile phase and flow-cell properties is primarily determined by chromatographic considerations and the desired spectral information. In principle, the spectral window of the solvent can be very small for quantitative analysis as the measurement of a single wavenumber, e.g. the band maximum, is

Figure 1 IR transmission spectrum of water recorded using a flow cell with silver bromide windows and an optical pathlength of 10 μm.

sufficient. Contrary, qualitative information desires IR transparency over a much wider spectral region in order to determine the presence or absence of functional groups, or to identify a compound by its IR fingerprint region (1300–600 cm^{-1}). Obviously, the spectral window of the mobile phase is inversely proportional to the cell thickness and thus, an excess of sensitivity can be traded for more spectral information and vice versa. The experimental parameters in LC/IR are, therefore, a compromise between chromatographic and spectroscopic considerations giving maximum cell thickness and solvent transparency.[5–8]

In order to minimize the problems associated with eluent absorption, the choice of the solvent in flow-cell LC/IR is generally restricted to chlorinated alkanes and deuterated solvents. These solvents leave relatively wide windows in the spectrum, although even these eluents inevitably obscure parts of the spectral functional group region (4000–1300 cm^{-1}) and the fingerprint region. The use of a small percentage of a more polar modifier in the eluent, as is quite common in normal-phase liquid chromatography (NPLC), may already prohibit effective detection. Owing to the short optical pathlength, the absolute limit of detection in on-line LC/IR often is in the order of a few micrograms, which implies that analyte concentrations of 1–10 g L^{-1} have to be injected to obtain identifiable spectra.

Tran et al.[9] proposed a completely different flow-cell LC/IR technique with, potentially, higher sensitivity. Different from the conventional way of measuring the IR absorption over a certain wavenumber region, this technique, called IR thermal lens spectrometry, is based on the measurement of the temperature rise that is produced in an illuminated sample by non-radiative relaxation of the energy absorbed by molecules upon IR laser excitation. Detection is carried out either directly, i.e. at a specific wavelength where only the analyte of interest absorbs, or indirectly, i.e. at a wavelength where only the mobile phase absorbs. Obviously, no spectral information is obtained with this quantitative technique, and the wavenumber region that can be covered with IR-tunable lasers is limited.

In conclusion, flow-cell IR detection is not a widely applied technique in LC as result of the interference of absorption bands of the mobile phase and the limited sensitivity of IR spectroscopy. Applications largely focus on dynamic systems where low detection limits are not crucial and solvents appropriate for IR detection can be selected more or less freely, that is, without having unacceptable detrimental effects on the analytical performance. Examples of such techniques are gel permeation chromatography (GPC), also referred to as size-exclusion chromatography (SEC), and flow-injection analysis (FIA). An important feature of the flow-cell LC/IR technique is the ability to monitor the elution of compounds with specific structural characteristics, i.e. functional groups. Besides, apart from regions of solvent opacity, spectra can be obtained instantaneously from any point in a chromatographic peak.

2.2 Solvent-elimination Approach

The compatibility and time-domain difficulties connected to flow-cell IR detection can be circumvented by coupling LC and IR spectrometry via a substrate suitable for IR detection. In this indirect approach, the eluent is eliminated and the chromatographically separated compounds are immobilized on the substrate prior to the collection of IR spectral data. The immobilization of the chromatogram is accomplished by using an interface which evaporates the eluent and continuously deposits the column effluent onto the moving substrate. In this way, interference-free IR spectra of the deposited compounds can be recorded independently from the LC conditions and the sensitivity of the FTIR spectrometer can be fully exploited. A schematic of a solvent-elimination LC/IR set-up is depicted in Figure 2.

Besides the possibility to acquire full spectra, there are some additional advantages of the solvent-elimination approach with respect to flow-cell IR detection. By careful control of the interface performance and the speed of the substrate, concentrated deposits may be obtained which will enhance analyte detectability. Spectral analysis can be performed without any time constraints since the chromatogram is stored on the substrate. This implies that signal averaging can be used and analyte spots can be analyzed repeatedly. For instance, after rapid screening of the deposited trace applying low spectral resolution and only one scan per spectrum, high-resolution spectra with a high S/N can be recorded for a few interesting parts of the chromatogram. Moreover, spectrometric analysis of the stored chromatogram in principle can be carried out at any convenient time or place, which may be helpful when suitable IR facilities are limited and spectrometers have to be shared.

Figure 2 Schematic representation of a set-up for solvent-elimination LC/IR; LC, liquid chromatograph; IF, interface; Sub, deposition substrate; T, transfer; S, spectrometer.

Evidently, the solvent-elimination approach to LC/IR is (technically) more complicated than on-line IR detection. It requires an interface which should adequately effect the evaporation of the eluent and, at the same time, maintain the chromatographic resolution during the deposition process. In this respect, the LC flow rate, the composition of the eluent, the nature of the analytes and the substrate material are important factors. For example, small volumetric flows of a volatile solvent may be readily evaporated, while rapid elimination of aqueous eluents will require an interface with enhanced solvent-elimination power. Elimination of the eluent may also be hampered by the presence of nonvolatile additives such as buffer salts. Next to eluent evaporation, ideally the interface also should provide compound deposition into narrow spots in order to minimize band broadening and achieve optimum IR sensitivity. However, complete eluent evaporation and compact analyte deposition may well be irreconcilable goals. Therefore, in solvent-elimination LC/IR reduced flow rates, nonbuffered eluents and/or eluents with a low (or even zero) water percentage are frequently used.

The compounds analyzed by solvent-elimination LC/IR, of course, should be considerably less volatile than the eluent to accomplish their deposition. Since LC is used for nonvolatiles in particular, this condition is generally met. The quality of the used substrate should not be affected by either the eluent or the deposited compounds. The substrate also must be compatible with the selected IR mode without introducing additional interferences. Furthermore, the physico-chemical properties of the substrate may influence the efficiency of analyte immobilization. For instance, residual eluent easily spreads over a substrate with a hard and smooth surface, while it may be effectively sorbed by a powder.

During the last decades, the combination of LC and IR via solvent elimination has been pursued by several research groups, which designed quite a number of different interface concepts with varying success. The common goal of all these LC/IR systems is to sensitively acquire IR spectra of mixture constituents that are free from spectral interferences and can be used for identification purposes. Through the years, the IR detection limits obtained with solvent-elimination LC/IR have improved gradually from the microgram to the low- or sub-nanogram range. Despite the progress, today there is no single ''perfect'' solvent-elimination interface available: every described system has its specific limitations with respect to, for example, flow rate, composition of the eluent and/or achievable sensitivity. The research activities in the field, which until now have been dominated by the problem of simultaneous eluent-evaporation and compound-deposition, are still on-going. Nevertheless, during the last years, several new commercial interfaces based on the solvent-elimination approach have been introduced.[10,11]

3 FLOW-CELL TECHNIQUES

3.1 Cell Types and Infrared Detection Modes

A variety of flow cells, differing in optical material, pathlength and cell volume, is available for LC/IR detection purposes. The cells, including corresponding beam condensing optics, generally fit in the standard optical bench of the IR spectrometer. The distance between the flow cell, i.e. the IR spectrometer, and the LC system is kept as short as possible in order to minimize deterioration of the chromatography. As noted in section 2.1, the selection of a certain cell type and, particularly, the optical pathlength, depends on the required information.

The choice for a specific window material is mainly determined by the properties of the LC eluent and the spectral region that has to be monitored. A fully IR-transparent material such as potassium bromide (KBr), for instance, cannot be used with RPLC. Instead, more expensive water-insoluble materials such as calcium fluoride and zinc selenide (ZnSe) have to be chosen. The optical and physical properties of some commonly used IR-window materials are presented in Table 1. In all cases, in order to obtain an identifiable IR spectrum a minimum amount of analyte has to be present in the

Table 1 Optical materials for use in IR flow cells

Material	Spectral window (cm^{-1})	Solubility in water	Sensitive to
Silver chloride	4000–350	slightly soluble	complexing agents
Calcium fluoride	4000–1100	insoluble	ammonium salts; acids
Quartz	4000–2400	insoluble	hydrofluoric acid; hot sulfuric acid
Potassium bromide	4000–400	very soluble	water; methanol
Zinc selenide	4000–450	insoluble	acids; strong alkalis
KRS-5	4000–250	slightly soluble	complexing agents
Polyethylene	630–30	insoluble	organic solvents

detection cell during the time of measurement. According to Beer's law, the minimum identifiable concentration decreases when the pathlength of the cell is increased. However, extending the pathlength also results in an increase of the eluent absorbance, thus limiting the spectral window. Commonly, the volume of the flow cell has to be minimized to such an extent that only a small part (1% or less) of an LC-peak volume will fill the cell. Obviously, this places a significant limitation on the obtainable sensitivity. Through the use of microbore LC columns, the volume of the flow cells and LC peaks can be made more compatible and, for that reason, micro-LC/IR is often preferred. Besides a reduced solvent consumption, microbore LC may also offer higher peak concentrations in the cell. At the same time, however, it should be noted that the sample capacity (both in mass and volume) of micro-LC columns is rather limited.[12]

Two types of commercially available flow cells can be distinguished for LC/IR: transmission cells and attenuated total reflection (ATR) cells. The principle of a transmission flow cell is depicted in Figure 3. The basic part of the cell consists of an IR-transparent cavity or two IR-transparent windows separated by a metal spacer. The optical set is mounted into a metal body between flexible rings to prevent breakage. The LC effluent enters and exits the cell via capillary tubes connected to an assembly of universal fittings and the IR beam passes perpendicularly through the LC flow. Additional equipment can be purchased for operation at elevated temperature and pressure. Zero-dead-volume (ZDV) flow cells for IR detection have been developed to minimize the volumes needed to connect the cell to the column, which is very important when microbore LC is used. In this type of cell the LC effluent is directly led into the cavity of the optical element (Figure 4). Flow cells, micro-flow cells and ZDV-cells can be purchased in many variations, rigid and demountable, differing in window material, pathlength (0.001–0.5 mm) and internal volume (0.1–10 μL). Micro-cells are generally used in combination with a beam condenser to obtain a sufficiently high energy throughput and thus enhance the S/N of the recorded signal and/or spectra.

The second type of flow cell is based on the phenomenon of ATR and is called cylindrical internal reflectance cell or CIRCLE® cell.[13] The principle of the CIRCLE® cell is depicted schematically in Figure 5. The cell consists of a cylindrically shaped IR-transparent rod crystal with cone shaped ends that is incorporated in a boat-type cell body made of stainless steel (SS) or glass. The effluent of the LC column flows around the optical crystal while the interrogating IR beam enters the crystal at one end, reflects off the internal surfaces of the crystal and then exits at the other end. The cell body fits into a small optical bench with special input and output optics. Several crystal materials can be used but ZnSe is commonly preferred because of its high IR transparency, high

Figure 3 Cavity flow cell for IR transmission detection.

Figure 4 Schematic representation of a ZDV flow cell for IR transmission detection.

Figure 5 Schematic representation of an IR flow cell for cylindrical internal reflectance detection (CIRCLE® cell).

refractive properties and insolubility in water. CIRCLE® cells can be equipped with heating or cooling jackets too. The cell design tends to involve a relatively large sample volume and efforts have been made to reduce the internal volume of CIRCLE® cells to 1–25 μL in order to allow their efficient application in LC. The effective pathlength of a CIRCLE® cell is defined by the number of reflections in the optical element and, therefore, sensitivity can be enhanced by using longer optical elements. These, however, also imply an increased cell volume and, thus, extra broadening of the LC peaks. CIRCLE® cells cannot be used for quantification in a straightforward manner since the penetration depth of the IR radiation in the LC eluent is limited (typical 1–5 μm) and wavelength dependent. Special algorithms are used to compensate for this.

3.2 Use in Liquid Chromatography

As outlined in the previous sections, flow-cell IR detection is not the principal choice in LC. Yet, it is a valuable alternative and additional method to obtain specific quantitative and structural information on analytes. In view of the relatively poor sensitivity, IR detection is restricted to applications in which low detection limits are not required. In GPC, for example, column capacities and sample concentrations are usually high. Gel permeation chromatography/infrared (GPC/IR) is well suited for the characterization and quantification of compositional changes throughout a (bio)polymer mass distribution. Besides, the structural differences between the polymer components (usually homologues) often are small which implies that one or two spectral windows will suffice for specific detection.

Applications of on-line LC/IR, including automatic subtraction of the solvent background, had already been described in the mid-1970s.[1,2] Injected amounts at submicrogram level were found to be feasible for detection in both NPLC and RPLC separations. In subsequent studies, Taylor et al.[13,14] demonstrated that microbore LC (column i.d., less than 1 mm) offers improved sensitivity compared to conventional LC (column i.d., 4.6 mm) because of the higher sample concentration in the detector cell. Furthermore, use of halogenated hydrocarbons as eluent was shown to offer better spectral specificity owing to the higher IR-transparency of these solvents. A reasonable number of applications of flow cell LC/IR in a variety of disciplines has been developed since. Saunders and Taylor,[15] for example, applied on-line GPC/IR with tetrahydrofuran (THF) as mobile phase for the determination of the nitrogen content of cellulose nitrates. A cylindrical micro flow cell with a pathlength of 1 mm and an internal volume of 4 μL was employed in combination with a beam condenser. The extinction of the O–N–O asymmetric stretching band was used for the quantification of primary and secondary carbon nitration. An improved resolution and quantification was achieved by spectral derivatization. On-line GPC/IR is also a viable analysis method in the polymer field. One method employs high-temperature GPC with flow-cell IR detection to characterize the molecular weight distribution of high-density polyethylenes.[16] Tri- and dichlorobenzene were used as mobile phase as these solvents do not exhibit interfering absorption in the CH_2-stretching band region (3000–2700 cm^{-1}). Furthermore, a quartz flow cell with a relative long pathlength of 1 cm could be used in order to enhance the sensitivity. The method compares favorably with gradient elution fractionation combined with ^{13}C-NMR spectroscopic characterization.

The strong IR absorption of water, methanol and acetonitrile, limits the application of on-line reversed-phase liquid chromatography/infrared (RPLC/IR) to the analysis of samples with relatively high analyte concentrations, such as wines, beverages and cellulose solutions. Various examples of this type of analysis have been described in the literature. Recent applications are the identification and quantification of sucrose, glucose and fructose in soft drinks,[17] and the specific analysis of monosaccharides, alcohols and organic acids in wine.[18] In both studies, separations were achieved with ion-exchange columns using an aqueous eluent. IR detection was performed with a 25-μm pathlength flow cell and minimal identifiable concentrations of typically 1 g L^{-1} were obtained.

When a high sensitivity or selectivity is required, conventional RPLC solvents cannot be used with IR flow cells. Therefore, alternative methods have been developed to circumvent the IR-opacity problems imposed by the aqueous mobile phase, while maintaining the advantages of on-line detection. One approach is the extraction of the analytes into a more IR-transparent solvent. Another approach is the use of deuterated solvents which virtually have the same chromatographic properties but do not absorb in the spectral region of interest. An example of the first method is the dynamic extraction of the analytes from the aqueous effluent into chloroform or carbon-tetrachloride.[19] The on-line liquid–liquid extraction (LLE) is carried out in an extraction coil followed by continuous separation of the aqueous and organic phases by a hydrophobic membrane. Subsequently, the organic phase, carrying the extracted analytes, is monitored in a common IR flow cell. A basically different post-column extraction method has been developed by Messerschmidt.[20] In this method, the RPLC effluent is diluted with water, and the analytes of interest are trapped on several small solid-phase extraction (SPE)

columns. These columns are dried with a flush of nitrogen, and sequentially eluted with a small volume of tetrachloromethane into an IR flow cell allowing the individual spectra of the analytes to be recorded. An additional advantage of this method is the improved minimal identifiable concentration as a result of analyte concentration on the SPE column. This technique has been successfully applied by DiNunzio[21] for the separation and identification of active compounds and degradation products in pharmaceutical samples.

In on-line LC/IR, deuterated solvents can be attractive substitutes for conventional (hydrogenated) solvents. The absolute absorbance of deuterated solvents is usually smaller and, more importantly, their IR absorption bands are shifted to different spectral regions. Additionally, deuterated solvents and their hydrogenated counterparts show very similar elution properties. With respect to on-line extraction procedures, the use of deuterated eluents has advantages in terms of simplicity, speed and maintenance of the chromatographic resolution. A major drawback is their high price. A detailed study on the utility of deuterated eluents in micro-column RPLC, NPLC and GPC with flow-cell IR detection was carried out by Fujimoto et al.[22] It follows that the problem of interfering solvent absorption bands can be (partially) solved by a deliberate choice of a deuterated eluent. Chen and Kou,[23] for instance, used deuterated methanol and water instead of the nondeuterated solvents to overcome the strong interfering absorptions that hinder the effective detection and quantification of lipid fractions by on-line LC/IR. Remsen and Freeman analyzed proteins using on-line gel permeation chromatography/Fourier transform infrared (GPC/FTIR) with a deuterium oxide eluent to remove water and other detection-interfering low-molecular-weight compounds and to achieve a rapid hydrogen exchange.[24] Amounts of 50 μg per protein could be detected in the amide-I region between 1600 and 1300 cm^{-1}, and important information on the protein conformation could be obtained.

3.3 Use in Flow-injection Analysis

FIA is a well-established analytical technique, based on the automated injection of a series of samples in a continuous carrier stream. In FIA various detectors are used, mainly for quantitative purposes. Amongst these detection modes, flow-cell IR is not a frequent choice because of the interfering solvent absorptions and the relative poor sensitivity compared to UV/VIS and fluorescence detection.[25] In several cases, however, on-line flow-injection analysis/infrared (FIA/IR) is an appropriate alternative for the rapid determination and quantification of a specific analyte in a simple mixture. In FIA, there is no need for an eluting solvent and, therefore, in contrast with LC, a carrier solvent suitable for IR detection can be selected quite easily. In this respect, FIA/IR has a wider application range than LC/IR. Still, the flow cells used in FIA/IR are not different from the ones used in LC/IR and the resemblance in detection approach is evident. Commonly, FIA/IR is applied for single-component analysis but since IR spectra comprise a range of absorption frequencies, multi-component analysis can in principle be carried out as well. Obviously, the IR absorption bands of the carrier should not spectrally interfere with the marker band of each analyte.

Guzman et al.[26] compared the characteristics of transmission and CIRCLE® cell detection in FIA/IR for multicomponent analysis of ternary solvent mixtures. With tetrachloromethane as carrier, the transmission cell provided better sensitivity in the continuous-flow mode. The shorter effective pathlength of the CIRCLE® cell was compensated for by applying the stopped-flow technique which allowed data averaging and, thus, enhancement of the S/N of the ATR spectra. Analyte concentrations of 1–2% (v/v) could still be measured.

The principles and applications of flow-cell FIA/IR have been studied extensively by the group of de la Guardia.[27–33] The effects of flow rate, injection volume, cell volume and optical pathlength on the performance of the FIA/IR analysis of *o*-xylene in solutions of hexane, were investigated.[29] Further optimization was achieved in the development of a method for the automated determination of benzene in gasoline.[30] In a further study, incorporation of an analyte-enrichment step was proposed to improve the detection limits of on-line FIA/IR.[31,32] Preconcentration was carried out by trapping the analytes on an SPE cartridge. After drying of the cartridge with nitrogen gas, the analytes were eluted with dichloromethane and detected by IR transmission spectroscopy using a micro flow cell. For aqueous solutions of the pesticide carbaryl and its major metabolite 1-naphthol, detection limits of 0.36 mg L^{-1} and 1.6 mg L^{-1}, respectively, were obtained after preconcentration of 100-mL samples. Quantification was achieved by specific detection of the bands at 1744 cm^{-1} (carbaryl C=O) and 1276 cm^{-1} (1-naphthol C–O) (Figure 6). FIA/IR is also a useful alternative for the quantitative analysis of mineral oil and grease.[33] Analogous to the International Organization for Standardization (ISO) procedure for the quantitative analysis of mineral oil in water and soil, this method is based on measurement of the aromatic, olefinic and aliphatic C–H stretching bands in the 3200–2700 cm^{-1} region. The samples were extracted with tetrachloromethane by LLE or microwave-assisted extraction. Next, the extracts were analyzed by FIA/IR at a sampling frequency of 60 h^{-1} using a quartz flow

Figure 6 Absorbance spectra of carbaryl (—) and 1-naphthol (- - -) dissolved in $CHCl_3$ showing peaks at (A) 1741 cm^{-1} and (B) 1276 cm^{-1}. (Reproduced by permission of Elsevier Science from Y. Dagbouche, S. Garrigues, M. de la Guardia, *Anal. Chim. Acta*, **314**, 203–212, © 1995.)

cell with a 10-mm pathlength. The detection limit was 1 mg L^{-1} when 300 µL of the extract was injected.

Miller et al.[34] used FIA/IR for the simultaneous detection of succinylcholine chloride and bethanechol chloride, two pharmaceutically important compounds. The compounds were specifically monitored at 1075 cm^{-1} and 953 cm^{-1}, respectively, using a CIRCLE® cell. The detection limit was about 0.02% (w/v) at a throughput of 60 samples per hour. FIA/IR was also applied to the quantification of acetylsalicylic acid, caffeine and paracetamol in pharmaceutical formulations.[27,28] Using a chlorinated solvent the extinction of a characteristic absorption band could be measured for each of the analytes in the 1800–1500 cm^{-1} region. Commercially available flow cells with an optical pathlength of 0.117 mm (5 µL) or 0.17 mm (7.2 µL) were used. Two FIA/IR methods for automated analysis in clinical and process chemistry have been developed by Kellner et al.[35,36] The first method aimed for the determination of glucose and urea after on-line enzymatic digestion to gluconic acid and ammonium carbonate, respectively. A 25-µm pathlength transmission cell was used to monitor the aqueous flow from the enzyme detector. The performance of the system was satisfactory for relative clean samples such as standard solutions, fruit juices and soft drinks. However, for routine application, for example in blood analysis, further improvement of the reproducibility is still required. The second FIA/IR method was used to determine the amyloglucosidase activity during starch hydrolysis processes. The IR flow cell (pathlength, 49 µm) was constructed of two different window materials in order to compromise between high transparency (ZnSe) and low reflectivity (calcium fluoride). Because of the high viscosity of the starch solutions, a stopped-flow method was used to obtain maximum reproducibility and sensitivity. The changes in the IR-spectra of the process mixture appeared to be directly correlated with the enzyme activity.

4 SOLVENT-ELIMINATION TECHNIQUES

4.1 Deposition Substrates and Infrared Detection Modes

The solvent-elimination approach in LC/IR involves the use of an eluent-evaporation interface that deposits the LC-separated compounds onto an IR-compatible substrate. With most described set-ups, after immobilization of one or more chromatograms, the substrate is transferred to the IR spectrometer where spectra from the deposited spots are recorded. The deposited traces on the substrate may be moved (stepwise) through the interrogating IR beam so that, when scanning is complete, continuous IR chromatograms can be reconstructed by computer software. In some designs, IR detection is executed during the immobilization process, within 5–20 s after deposition, allowing spectra to be obtained in real time. Obviously, such a design requires a dedicated detector set-up. Dependent on the type of substrate used (see below) and/or size of the deposited spots, often special optics, such as a (diffuse) reflectance unit, a beam condensor or an IR microscope, are used to scan the deposited compounds.

Basically three types of substrates and corresponding IR modes are used in solvent-elimination LC/IR: powder substrates for diffuse reflectance Fourier transform infrared (DRIFT) detection; metallic mirrors for reflection/absorption (R/A) spectrometry; and IR-transparent windows for transmission measurements. In early solvent-elimination LC/IR designs DRIFT detection of analytes on potassium chloride (KCl) powder was used, but today other, more convenient, detection modes are preferred. DRIFT as such is one of the most sensitive IR modes and sub-microgram identification limits can be achieved when the residual solvent is evaporated quickly from the powder. If the eluent is not highly volatile, it can draw analyte away from the KCl powder surface into the substrate. This will limit the sensitivity, because the effective penetration depth of a DRIFT measurement is not more than 100 µm. To overcome this problem, diffuse transmittance spectrometry has been applied instead of DRIFT, using a layer of KCl powder on an IR-transparent substrate.[37] The main limitations of DRIFT detection in LC/IR, show up during application. Reproducibility is hard to control since factors such as sample homogeneity, sample load and compactness of the powder layer significantly influence the DRIFT analysis. Reorientation of the DRIFT

matrix as a result of sample deposition may lead to a poor background compensation. Careful filling of cups or trays with the powder substrate is very time-consuming and has to be repeated for every analysis. Finally, common substrates such as KCl powder cannot be used in combination with aqueous eluents. In view of the overriding importance of RPLC, this is a very serious restriction. Some authors have used diamond powder as a water-resistant DRIFT substrate, but it is expensive (and thus not disposable) and not easy to clean.

Front-surface aluminum mirrors, which are suitable for R/A detection, are compatible with aqueous eluents and are relatively easy to handle. Compound deposition on this type of substrate requires efficient solvent-elimination interfaces because residual solvent will easily spread over the hard and smooth reflective surface. The band intensities in the R/A spectroscopy are largely governed by a double-pass transmittance mechanism, so that spectral data analogous to transmission data are obtained. Some useful results of solvent-elimination LC/IR using mirrors have been reported, although several authors[38–40] have reported evidence of band asymmetry and spectral distortions. Aspects such as specular and diffuse reflection from the analyte, thickness and microcrystallinity of the spot, and optical characteristics of the substrate affect the shape and intensity of R/A spectra obtained from analytes on aluminum mirrors. The use of an IR-transparent germanium disc with a reflective backing has been proposed in order to reduce spectral distortions. This type of disc is used in the commercially available LC-Transform™ LC/IR interfaces.[10] The cleaning of aluminum mirrors in between analyses is quite delicate: the thin metal layer is fragile and can be damaged easily by rubbing.

Most favorable results in solvent-elimination LC/IR are obtained with IR-transparent deposition substrates that allow straightforward transmission measurements. So far mainly KBr and ZnSe windows have been applied in experimental LC/IR set-ups. These substrates have a hard and smooth surface and, therefore, eluent elimination has to be fast to achieve proper depositions. ZnSe is a water-resistant, inert material, while KBr usually cannot be used in combination with RPLC. Deposited compounds on ZnSe can be removed simply, with water or alcohol, so that one window can be used repeatedly. With ZnSe, good-quality IR spectra with symmetrical band profiles can be recorded from deposited spots. When the size of the sample spots is small and microscopic optics are used for measurement, the sensitivity of ZnSe transmission measurements is higher than the sensitivity of DRIFT measurements.[40] ZnSe windows also cause fewer spectral artifacts than mirror substrates for R/A detection.[39] Many LC/IR studies demonstrated that spectra obtained using ZnSe, closely resemble conventional KBr-disk transmission spectra. Consequently, existing spectral libraries and search programs can be used for identification purposes, which is very important for the acceptance of IR as a valuable detection technique.

The quality and appearance of spectra obtained with solvent-elimination LC/IR will be influenced by the morphology of the deposited analytes. The morphology will depend primarily on parameters such as eluent composition, evaporation rate, temperature and nature of the substrate and the analytes. During solvent elimination some compounds will form nice crystals while others will deposit as an amorphous layer. Also, some analytes will deposit as a smooth film, whereas others may form irregular clusters. When the spot thickness exceeds a certain level, the effect of light scattering may become apparent. A compound may also exhibit polymorphism so that mutually (slightly) different spectra can be obtained for the same compound. In general, IR detection of deposited compounds on IR-transparent substrates does not pose serious problems. However, analyte morphology should always be taken into consideration during spectral interpretation.

In solvent-elimination LC/IR the identification limits usually improve when the width of the analyte spots is decreased. A prerequisite for this gain is the use of the appropriate detector and sampling optics. Optimum solvent-elimination interfaces can produce analyte spots with a width as small as 100–300 μm. For these deposits, the focus of a conventional beam condensor is too large and the use of an IR microscope is indicated. Frequently, the sensitivity enhancement is rationalized by considering the relatively increased spot thickness only (Beer's law!), but this approach is too simple. From more complete S/N considerations it follows that the good sensitivity of IR microscopic detection essentially results from the low noise level of the IR detectors in IR microscopes.[4] In other words, to achieve the most sensitive IR detection in LC, the width of the analyte deposits should have the same dimensions as the microscope detector area (typically, 100–200 μm). Of course, as with any IR experiment, the S/N ratio also can be improved by increasing the measurement time (signal averaging). As outlined in section 2.2, this advantage can be exploited to its full extent in solvent-elimination LC/IR, although at the cost of an increased time of analysis.

4.2 Early Interfaces

The solvent-elimination systems that were developed in an early stage, generally used KCl-powder substrates for DRIFT detection or flat KBr windows for transmission detection. The first working interface for the coupling of NPLC and IR was designed by Kuehl and Griffiths.[3,41]

The organic eluent was led through a heated concentrator tube and dropped into a series of cups filled with KCl powder suited for DRIFT analysis. A carousel rotated the cups into the IR spectrometer where identifiable spectra could be recorded for sub-microgram amounts of analyte. In order to allow for RPLC separations, the aqueous effluent was first on-line extracted with dichloromethane which, after continuous phase separation, was directed through the concentrator to the KCl cups.[42] For extracted compounds good-quality spectra were obtained. The carousel–DRIFT method was also adopted for narrow-bore NPLC (use of 1-mm i.d. column) by reducing the size of the KCl cups and by omitting the concentrator tube.[43] Using a similar set-up, Kalasinsky et al.[44,45] coupled both narrow-bore NPLC and RPLC with DRIFT. The KCl-powder substrate was held either in a ''train'' of compartments or in a continuous trough. Aqueous eluents could be used by on-line conversion of the water into methanol and acetone via a post-column reaction with 2,2′-dimethoxypropane (DMP). The identification limits of these systems were 1–3 μg, typically.

The early DRIFT-based systems for the first time demonstrated that solvent-elimination LC/IR can provide (much) better sensitivity and spectral quality than flow-cell based LC/IR. However, the systems were mechanically complex and tedious to work with, and DRIFT detection appeared to be strongly affected by small disturbances of the KCl-powder surface and by the presence of (residual) water.

Jinno et al.[46–47] proposed the use of micro-LC columns (i.d., 0.3 mm) in solvent-elimination LC/IR in order to alleviate the problem of the evaporation of large eluent volumes. The effluent ($5\,\mu L\,min^{-1}$) from either a GPC or an NPLC was led directly to a moving KBr plate which was covered by a stream of heated nitrogen. Subsequently, the plate with the deposited track was scanned by IR transmission spectroscopy using a 3 × beam condensor. The potential of the approach (termed ''buffer-memory'' technique) was illustrated by the analysis of a mixture of dithiocarbamate metal complexes by three spectroscopic techniques.[47] In a modified set-up the linearly moving KBr plate was replaced by a rotating KBr disk which, after the chromatographic run was finished, was transferred to a special rotation module in the IR spectrometer.[48] In order to permit the use of RPLC, a SS wire net (WN) was used instead of an KBr window.[49] IR transmission measurements were possible because after deposition and drying the analytes were partly suspended in the metal meshes.

The ''buffer-memory'' technique demonstrated the usefulness of the storage of a continuous chromatogram on a flat substrate. Besides, it was considerably simpler than the DRIFT methods. However, at least several micrograms of analyte were needed for a positive IR identification. These amounts often exceeded the sample capacity of the micro-columns and required unrealistically high concentrations to be injected.

4.3 Spray-type Interfaces

When using the ''buffer-memory'' technique for compound deposition on flat substrates, it is not possible to eliminate organic or aqueous eluents at flow rates higher than about $5\,\mu L\,min^{-1}$ without spreading the compounds over a large area of the substrate surface. To achieve a more viable coupling of LC and IR, the use of interfaces with enhanced evaporation power is essential. The solvent-elimination interfaces developed in the last decade all use some kind of spraying to induce rapid eluent evaporation. Heat, gas, electric potential and/or ultrasonic vibrations are used to break up the LC eluent stream into small droplets. Some designs incorporate existing (commercial) equipment, while others have been built from scratch.

In the thermospray (TSP) interface, originally developed for liquid chromatography/mass spectrometry (LC/MS), a directly heated tube evaporates part of the column effluent to an expanding vapor causing nebulization of the remaining effluent. As a result, a mist of desolvating droplets emerges from the tube. In the TSP-based LC/IR systems, nebulization is performed at atmospheric pressure and the spray is directed towards a deposition substrate. Eluent flow rates of up to $1\,mL\,min^{-1}$ can be handled. Griffiths and Conroy[50] reported preliminary results on the use of TSP for LC/IR, but the first really working interface was introduced by Jansen.[51] With a home-made TSP, the LC effluent was sprayed on a SS IR-reflective tape which moved through an optical accessory in the IR spectrometer (Figure 7). Most of the eluent was eliminated directly by the TSP and residual solvent was evaporated off the tape by heating. The immobilized chromatogram was monitored

Figure 7 Schematic of TSP–moving belt interface for LC/IR; 1, moving SS tape; 2, TSP; 3, heater; 4, IR reflectance cell mounted in the IR spectrometer.

continuously and full IR spectra were recorded. Several simple polymer samples (20–80 μg injected) were analyzed by GPC/IR using an organic eluent at a flow rate of 0.5–1 mL min^{-1}, but some low-molecular-weight monomers were too volatile to be deposited. The characterization of two Irganox-type polymer additives (100 μg each), which were separated by RPLC using an eluent (0.5 mL min^{-1}) with 30 vol% water, was also shown. Robertson et al.[52] further optimized the TSP–moving belt interface by studying the effect of the TSP temperature and distance to the substrate. The system was used for the analysis of amino acids, saccharides, carboxylic acids, antioxidants and polymers,[53,54] and analyte identification could be achieved down to concentrations of 50 μg mL^{-1} or about 2.5 μg injected.

The main advantage of the TSP-based systems is that relatively high flow rates (0.5–1 mL min^{-1}) of both organic and aqueous eluents can be handled and conventional-size LC can thus be used. Furthermore, spectral data are acquired during the run, which gives the IR detector an essentially on-line character. On the other hand, the high temperature of the TSP may induce analyte losses by evaporation or thermal degradation and the analyte spots on the moving tape are still quite large which results in a moderate IR sensitivity.

The particle beam (PB) interface was modified for LC/IR by de Haseth et al.[55,56] and Wood.[57] In this interface the LC eluent is nebulized by helium and directed into a desolvation chamber where most of the liquid is vaporized. The mixture of gas, vapor and condensed analyte molecules (i.e. particles) is accelerated into the momentum separator where the analytes travel straight through the skimmer cone, while the gas and vapour are pumped away. For IR detection an IR-transparent substrate is placed in the particle-beam path to collect the analytes of interest (Figure 8) and after deposition, the substrate is transferred to the IR spectrometer for analysis. Until now stationary substrates have been used in liquid chromatography/particle beam/infrared (LC/PB/IR), that is, no complete chromatograms, only fractions, were analyzed. The particle beam/infrared (PB/IR) interface can effect the elimination of aqueous eluents at flow rates of up to 0.3 mL min^{-1} as was demonstrated by the analysis of erythrosin B and *p*-nitroaniline (50 μg each) by RPLC/IR.[56] Since the PB interface has strong eluent-elimination capacities, it was believed that interference caused by buffers might be small.[58] The interface indeed appeared to be able to process a 0.3 mL min^{-1} flow of buffered eluent, but the buffer salts were never completely eliminated. Best results were obtained with eluents buffered with ammonium acetate, although buffer bands were clearly present in the IR spectra recorded

Figure 8 Schematic of PB interface for LC/IR.

from microgram amounts of analyte. When phthalate or phosphate buffers were used, the analyte spectra were completely dominated by absorption bands of the buffer salts. Spectral subtraction procedures could be used to recover spectra from 130-μg depositions but were unsuccessful at the 13-μg level. PB/IR has been used as a tool for the determination of protein structures.[59–61] For β-lactoglobulin and lysozyme it was shown that their structural integrity is maintained during the PB desolvation process and the subsequent deposition on the substrate. In addition, lysozyme appeared to retain its biological activity. The sample loads in these experiments generally were quite high (5–500 μg).

The PB interface can effectively remove both organic and aqueous solvents. However, relevant applications in LC/IR would still require the construction of a device that allows the continuous deposition of a complete chromatogram on a moving substrate. The PB/IR analysis of compounds at the nanogram level has been indicated,[55] but the reported sample quantities mainly are in the (high) microgram range. The modest analyte detectability no doubt is related to the fact that the efficiency of analyte transfer in the PB interface probably is 5–10% only.

The potential of electrospray (ESP) nebulization for micro-LC/IR was studied by Raynor and co-workers.[62] A high electrical potential is used to form a spray of charged droplets at the end of a capillary filled with flowing liquid. As a result of charge density, the initial droplets break up into smaller droplets which

Figure 9 Schematic of ESP interface for (a) micro-LC/IR (b) with the ESP tip in detail. (Reproduced by permission of Hüthig Publishing from M.W. Raynor, K.D. Bartle, B.W. Cook, *J. High Resolut. Chromatogr.*, **15**, 361–366, © 1992.)

facilitate solvent evaporation. Use of low flow rates (typically 1–20 μL min^{-1}) is indicated in order to obtain a stable ESP. The ESP is formed under atmospheric conditions and a sheath flow of nitrogen gas is applied to enhance eluent evaporation (Figure 9). The ESP interface was used to deposit the effluent from a micro-RPLC column onto a ZnSe plate.[62] After LC separation, 20-ng amounts of caffeine and barbital could be analyzed successfully using an IR microscope. Identification of 2 ng caffeine appeared to be possible, although subtraction of the interfering bands from a siliceous impurity was required. Stable ESP conditions were achieved with hexane, dichloromethane, acetonitrile, methanol and several aqueous solvents, but problems were reported for

Figure 10 Schematic of a narrow-bore NPLC and IR system with pneumatic nebulization; (a) side view during deposition; (b) top view of collection mirror. (Reproduced by permission from J.J. Gagel, K. Biemann, *Anal. Chem.*, **58**, 2184–2189, © 1986, American Chemical Society.)

pure water. Until now there have been no further studies on electrospray/infrared (ESP/IR) detection in LC.

During pneumatic nebulization a high-speed gas flow is used to disrupt the liquid surface and to form small, fast-moving droplets. Organic solvents can be rapidly evaporated by pneumatic nebulization, while removal of aqueous solvents is possible when the nebulizer gas is heated. Pneumatic nebulizers have been used in several solvent-elimination LC/IR designs, among which are the most successful so far. One of the first nebulizer-based LC/IR methods involved the continuous spraying of the effluent from a narrow-bore NPLC column on a rotating IR-reflective disk (Figure 10).[63] The effluent was mixed with nitrogen gas to form a fine spray and the immobilized chromatogram was analyzed by rotating the disk through a 3 × -condensed IR beam while recording R/A spectra. The system was tested with polycyclic aromatic compounds (200–800 ng each) which were separated using hexane–dichloromethane as eluent (30 μL min^{-1}). Good-intensity spectra were obtained, although some spectral deviations were observed. This pneumatic nebulizer design was improved to accomplish elimination of aqueous solvents.[38] A heated nitrogen flow served as an evaporation-enhancing and spray-focusing sheath gas.

Eluents containing up to 55% water could be handled at $30\,\mu L\,min^{-1}$ and a number of isomeric naphthalenediols (500 ng each) were separated and identified. Again the recorded R/A spectra showed anomalies. These spectral problems could be partially solved by using an IR-transparent germanium disk with a rear surface of aluminum as substrate.[64] This pneumatic nebulizer LC/IR design is commercialized by Lab Connections.[10] The instrument consists of a sample-collection module and an optics module for R/A analysis. So far the commercial interface has been applied mainly in the field of GPC/IR.[65,66] It was also used for the identification of triclosan, an antibacterial agent, in toothpaste.[67]

A simple but effective concentric flow nebulizer (CFN) for the coupling of narrow-bore LC and IR spectrometry was constructed by Lange et al.[68] The interface consists of two concentric fused-silica capillaries. The LC column effluent is led through the inner capillary and heated helium gas through the outer capillary (Figure 11a). The hot gas facilitates the evaporation of the solvent and the focusing of the spray emerging from the inner tube. To enhance the elimination of aqueous eluents, the CFN and the ZnSe substrate were placed in a vacuum chamber (Figure 11b). IR microscopy was used for optimum detection. The CFN can handle eluents with up to 100% water at a flow-rate of $50\,\mu L\,min^{-1}$ and identifiable spectra of analytes can be recorded down to the low-nanogram range. The CFN was also installed in an evacuated compartment which included the IR-microscopic optics and a motor to translate the ZnSe window.[69] With this system, an RPLC effluent ($50\,\mu L\,min^{-1}$) could be continuously deposited on the moving substrate. After immobilization of the chromatogram, spectral data could be collected without the need to transport the substrate from the Chromatograph™ to the IR spectrometer. To further improve the on-line character of the system, a modified CFN was installed on the optical bench of a Tracer® (Biorad, Düsseldorf, Germany) gas chromatography–IR interface which allows spectral acquisition in real time.[70] So far, only some preliminary results with this on-line LC/IR system have been reported. Unfortunately, proper analyte spectra cannot be obtained with the CFN/IR system when using nonvolatile buffers, because of strong co-deposition of buffer salts.[71] However, if sufficient vacuum pump capacity is applied, a 1 mM ammonium acetate buffer can be completely eliminated, although higher ammonium acetate concentrations cause interference.

Somsen et al.[39] proposed a spray-jet interface for the coupling of narrow-bore RPLC and IR spectrometry. In this interface a heated nitrogen flow provides pneumatic nebulization of the column effluent ($20\,\mu L\,min^{-1}$) which is led through a SS needle that

protrudes through a spray nozzle (Figure 12). With ZnSe as substrate and IR microscopy for detection, identification limits in the 10–20-ng range were achieved for quinones and polycyclic hydrocarbons. The narrow-bore RPLC/IR system was used for the impurity profiling of a steroids,[72] for the isomer-specific characterization of chlorinated pyrenes,[73] and for the identification of additives in polymer samples.[74] Furthermore, the suitability of the interface for GPC/IR was demonstrated by analyzing polystyrene oligomers.[74] When RPLC is applied, the spray-jet LC/IR system is limited with regard to the LC flow rate, the water percentage of the eluent and the handling of buffered eluents. In order to take away these limitations, a post-column LLE module (phase segmentor, extraction coil and phase separator), was inserted on-line and

Figure 12 Schematic of the spray-jet interface for narrow-bore LC/IR.

the organic phase, carrying the extracted analytes, was sent to the evaporation interface.[75] The resulting liquid chromatography/liquid–liquid extraction/infrared (LC/LLE/IR) system can handle eluents with high water percentages (20–100 vol%) at flow rates up to $0.2\,mL\,min^{-1}$ and provides identification of compounds at the sub-milligram per liter level. Since the salts are not extracted, nonvolatile buffers can be used without causing interference. The detectability of the analytes was further improved by incorporation of on-line SPE for analyte enrichment (Figure 13). With such a system, triazine herbicides, including several isomers, could be identified at the low-microgram per liter level in river water (Figure 14).[76]

In an alternative approach to improve the compatibility of the spray-jet interface with RPLC, the eluent flow rate was reduced to $2\,\mu L\,min^{-1}$.[77] To obtain a useful spray, a make-up liquid ($20\,\mu L\,min^{-1}$ of methanol) was added to the micro-LC effluent. As a consequence, the performance of the interface became independent of the water content of the eluent, so that gradient elution was possible. A micro-precolumn for on-line trace enrichment was applied to improve detection limits. With a 40-μL sample volume, good-quality IR chromatograms and analyte spectra were recorded at the low-milligram per liter level.

In an ultrasonic nebulizer a spray is formed by depositing the LC effluent on a transducer that is vibrating at ultrasonic frequencies. For LC/IR purposes, the spray is directed towards a substrate by a carrier gas. Castles et al.[78] used ultrasonic nebulization for the deposition of compounds separated by narrow-bore RPLC on a diamond-powder substrate suitable for DRIFT detection. Spectra of satisfactory quality were obtained

Figure 14 SPE and LC/LLE/IR chromatograms of river Meuse water samples spiked with five triazines: (a) 20 mL (30 μg L^{-1}), (b) 50 mL (6 μg L^{-1}) and (c) 100 mL (2 μg L^{-1}). for injections of 3 μg of analyte. In some instances, the complete and direct evaporation of the eluent by the ultrasonic nebulizer was not achieved because the vibrating surface was not uniformly effective and occasionally large droplets were formed which wetted the diamond powder. Dekmezian and Morioka developed an interface for high-temperature GPC/IR which involved an ultrasonic nebulizer.[79] The nebulizer was placed in a vacuum chamber and sprayed the column effluent on a set of heated KBr discs, which were subsequently analyzed by IR transmission spectrometry. The system was applied to the determination of compositional changes of ethylene–propylene rubbers. An interface comprising an ultrasonic nebulizer in a vacuum chamber is used by Lab Connections in their LC-Transform™ 300 Series.[10] This commercial device sprays

the chromatographic effluent on a rotating germanium collection disk suited for R/A analysis (see above). The system was used for the quantitative analysis of copolymers by GPC/IR[80] and for steroid analysis by RPLC/IR.[81]

5 STATE OF THE ART

In the contemporary practice of LC/IR both flow-cell and solvent-elimination approaches are applied. Since the flow-cell procedure cannot get around the detection limitations imposed by the LC eluent, it has developed into a special-purpose method with restricted applicability. The IR absorptions of any solvent invariably take up parts of the mid-IR spectral region and, therefore, the main power of IR spectroscopy, i.e. the reliable identification of compounds, cannot be fully exploited in flow-cell IR detection. Nevertheless, making use of the spectral windows of the eluent, flow-cell IR spectroscopy can serve as a moderately sensitive, compound-specific detection technique. Occasionally, it is used as a universal, fast and low-cost method to obtain quantitative and structural information on major constituents of samples. Various types of flow cells are commercially available, and the experimental set-up and practice of flow-cell LC/IR is relatively simple and well-suited for routine applications.

When the objective of IR detection in LC is the unambiguous identification of (low-level) constituents of mixtures, coupling via solvent elimination should be the approach of choice. Solvent elimination procedures offer the possibility

- to record spectra over the entire mid-IR region without interference from the eluent;
- to perform signal averaging in order to improve the S/N of the spectra; and
- to contain a relatively large part of the chromatographic peak within the IR beam.

As a result, the solvent-elimination approach provides a set-up which features increased sensitivity and enhanced spectral quality, two important conditions for effective analyte identification. The most recent commercial LC/IR systems which are presently available,[10,11] are solvent-elimination devices. Interestingly, also in gas chromatography and supercritical-fluid chromatography analyte-deposition-based IR detection has proven to be more sensitive and versatile than flow-cell-based techniques. On the other hand, one should realize that the vibrational information obtained after solvent elimination is different from the vibrational information obtained with flow-cell detection (condensed-phase spectra against solution-phase spectra). Recently, this difference was used to determine subtle molecular features of drug metabolites which were analyzed by both flow-cell and solvent-elimination LC/IR.[82]

Today, the vast majority of LC separations is carried out by means of RPLC and, not surprisingly, research in the field of LC/IR has concentrated on the development of interfaces that are suitable for the elimination of aqueous eluents. Table 2 summarizes the characteristics of the various solvent-elimination reversed-phase liquid chromatography/Fourier transform infrared (RPLC/FTIR) systems which have been developed during the last years. The systems based on TSP, PB and ultrasonic nebulization

Table 2 Characteristics of solvent-elimination RPLC/IR systems[a]

Type of interfacing	IR mode	Substrate	Eluent flow rate[b] ($\mu L\,min^{-1}$)	Limit of identification[b]		Refs.
				mass (ng)	conc ($mg\,L^{-1}$)	
Concentrator after LLE	DRIFT	KCl powder	800	100	10	42
Deposition after DMP	DRIFT	KCl powder	50	1000	1000	44

[b] Typical values.

can handle relatively high flows of aqueous eluents and allow the use of conventional-size LC, which evidently is an advantage. However, these systems often exhibit moderate, or even unfavorable identification limits and, therefore, their analytical applicability is limited. Until now, the most favorable results have been obtained with pneumatic nebulizers which essentially represent the state of the art in solvent-elimination LC/IR.

The pneumatic interfaces combine rapid solvent elimination with a relatively narrow spray. This implies that analytes can be deposited, for example on ZnSe, in a narrow track of spots and IR microscopy can be applied effectively to achieve mass sensitivities in the low-nanogram range. Bearing in mind that often only part of the injected amount of analyte is actually analyzed, this means that the mass detectability of these LC/IR systems approaches a level close to the minimum that can be identified by IR spectroscopy. The systems based on pneumatic nebulization are limited with regard to flow rate ($2-50\,\mu L\,min^{-1}$) and water percentage of the eluent. The tolerable water content of the eluent depends on the flow rate. Flow rates of $2-5\,\mu L\,min^{-1}$ of even pure water can be eliminated, but for $20-50\,\mu L\,min^{-1}$ flows of aqueous eluents, enhancement of the solvent evaporation efficiency is required, for example by mixing the effluent with nitrogen gas[38] or by placing both the nebulizer and the deposition substrate inside a vacuum chamber.[68] The tedious evaporation of water can also be circumvented by applying on-line LLE of the aqueous effluent with an organic solvent. Such a system allows much higher flow rates ($0.2\,mL\,min^{-1}$) and percentages of water (up to 100 vol%).[75,76] Of course, the required LLE module adds to the complexity of the system and the analytes must have a sufficiently high extraction efficiency. Solvent-elimination RPLC/IR with gradient elution poses the problem of the efficient evaporation of an eluent with a changing water content. One solution involves the increase of the temperature of the nebulization gas during the gradient run,[38] another the addition of excess methanol to a micro-LC effluent in order to mask the changes in its water content.[77]

The injection volumes that can be handled with micro- and narrow-bore LC columns, are at most $1-2\,\mu L$. The identification limits in terms of concentration units of the pneumatic nebulizer-based systems therefore are in the low-milligram per liter range, which is sufficient for a number of analytical applications.[72–74] By using the LLE-pneumatic nebulizer combination, the detectability can be improved to sub-milligram per liter levels because larger LC columns – and, thus, increased injection volumes – can be used. With an adequate trace-enrichment procedure such as on-line SPE, the LC/IR detection limits can be further improved down to the low-microgram per liter level.[76] The use of buffered eluents is generally avoided in solvent-elimination LC/IR, since buffer salts may seriously affect the deposition and detection of the analytes. With pneumatic nebulizers even volatile buffer salts are rarely completely eliminated. In fact, until now the LLE-pneumatic nebulizer combination is the only described LC/IR system which allows the use of nonvolatile buffer salts without introducing interfacing disturbances and/or spectral interference.[75,76]

Effective solvent elimination by the pneumatic nebulizers allows the use of deposition substrates with a hard and smooth surface such as ZnSe windows. With these substrates interference- and distortion-free transmission spectra are obtained which can be readily compared with conventional KBr-disk IR spectra. This implies that libraries of condensed-phase reference spectra can be used for spectral recognition and identification. Compounds of various nature such as quinones, steroids, drugs, polymer additives and herbicides have been analyzed successfully by pneumatic-nebulization-based LC/IR. The interfaces can handle most types of analytes, although too volatile compounds will be evaporated by the nebulizer gas and therefore will not be deposited on the substrate. Thermal degradation of analytes is commonly not observed during pneumatic nebulization, despite the fact that the nebulizer gas is heated to rather high temperatures (70–180 °C). Probably, due to the rapid evaporation of the solvent, the spray droplets are cooled considerably.

6 PERSPECTIVE AND FUTURE DEVELOPMENTS

In the last fifteen years, LC/IR has emerged as a potentially powerful tool for the specific detection of major components (flow-cell approach) or for the identification of (minor) constituents of complex mixtures (solvent-elimination approach). With respect to common LC detection techniques such as UV/VIS absorption detection, the sensitivity of flow-cell IR detection is rather poor and its merits therefore mainly lie in the ability to quantitatively monitor absorptions that are specific for the analyte or for a certain functional group. Since the limitations of flow-cell LC/IR are inherent in the technique, no vast improvements can be anticipated in the future. Some gain in performance may be achieved by optimization of the flow-cell design and use of advanced FTIR spectrometers, but these improvements will be modest and not essentially change the applicability of flow-cell IR detection. Employment of chemometrical techniques, however, may be useful particularly when the signal or spectrum is the result of the absorbance of two or more substances.

The usefulness of solvent-elimination LC/IR to provide structural information and/or identification of unknowns

has been demonstrated convincingly since 1990. Unfortunately, the development of coupling techniques proceeded, and still proceeds, quite slowly and until now most interfaces have been used only by their designers. Nevertheless, the difficulty of solvent-elimination LC/IR, i.e. simultaneous eluent evaporation and analyte deposition, seems to be a technical rather than a fundamental problem. In other words, the development of an overall effective and routinely applicable interface probably is a matter of time, effort and technological innovations. Of course, solvent-elimination LC/IR has to compete with other identification techniques of which today on-line LC/MS undoubtedly is one of the most important. Quite a number of LC/MS interfaces have been developed and commercialized, but still each interface has its specific limitations. Furthermore, MS techniques cannot discriminate between isomers. Hence, even with adequate LC/MS techniques available, there is a need for alternative and complementary detection techniques which independently confirm MS-based identifications and differentiate between structurally highly similar compounds. A recent study demonstrated that LC/IR can make a viable contribution to identification analysis in a research setting that includes MS and NMR.[82] Prerequisite for the successful implementation of IR detection was a good understanding of the relative strengths and weaknesses of each technique, and the integration of analysis in the total research program.

In order to enhance the acceptance of solvent-elimination LC/IR, several items of interest should be considered. The practicality of the technique for real-life samples should be demonstrated more extensively. The applications described so far[72–74,76] indicate that LC/IR can indeed be used for the characterization and unambiguous identification of target and unknown compounds. LC/IR is particularly useful for the distinction of isomeric compounds[77–79] which cannot be distinguished by LC/MS. Another item of attention is the development and use of appropriate on-line sample-treatment procedures to improve analyte detectability. Despite the low-nanogram identification limits, the detectability in concentration units of even the best LC/IR systems will not be sufficient to meet current demands in bio- and environmental analysis. On-line SPE can improve the concentration detectability by one or two orders of magnitude. Obviously, such an improvement is unlikely to be obtained by optimization of interfacing and/or IR detection only. The first studies indicating this advantage in both flow-cell and solvent-elimination IR-detection have already been reported.[31,32,76,77]

Concerning the viability of solvent-elimination LC/IR, the availability and use of commercial interfaces also is essential. The LC-Transform™ interface (Lab Connections) has been available now for several years, but unfortunately few applications have been reported. Because this solvent-elimination system uses a mirror substrate and standard IR equipment, both the IR sensitivity and spectral quality are limited. In a more viable approach an IR-transparent substrate should be used together with microscopic IR detection. Such a configuration is used by the Infrared Chromatograph™ interface (Bourne Scientific). In this commercial and automated design the LC column effluent is deposited on a moving ZnSe window which instantaneously passes through the focused beam of the IR spectrometer allowing spectra and IR chromatograms to be recorded in real time. The placement of the chromatograms on the substrate is controlled by computer which also keeps a record of the position of deposited compounds. The IR Chromatograph™ seems promising but, as it has been introduced only recently, it is still too early to assess its merits. The handling of the obtained spectral data also is a matter of concern in solvent-elimination LC/IR. The identification of analytes on the basis of their IR spectra often is a difficult operation. Therefore, the automated retrieval of spectra in reference collections, and the computerization of spectral interpretation are important. Several such procedures have already been introduced in the vibrational-spectroscopic field and high priority should be given to their implementation in the separation field.

Finally, it should be noted that the solvent-elimination approach in LC is not restricted to IR detection but can, in principle, be applied to any spectrometric technique which requires the compounds of interest to be present as deposits.[83] An example of such an analyte-deposition-based detection technique is matrix-assisted laser desorption/ionization (MALDI) MS. From a technical viewpoint the collector systems developed for the coupling of LC or capillary electrophoresis with MALDI/MS show a strong similarity with solvent-elimination LC/IR systems.

ABBREVIATIONS AND ACRONYMS

ATR	Attenuated Total Reflection
CFN	Concentric Flow Nebulizer
DMP	Dimethoxypropane
DRIFT	Diffuse Reflectance Fourier Transform Infrared
ESP	Electrospray
ESP/IR	Electrospray/Infrared
FIA	Flow-injection Analysis
FIA/IR	Flow-injection Analysis/Infrared
FTIR	Fourier Transform Infrared
GPC	Gel Permeation Chromatography

GPC/FTIR	Gel Permeation Chromatography/Fourier Transform Infrared
GPC/IR	Gel Permeation Chromatography/Infrared
IR	Infrared
ISO	International Organization for Standardization
LC	Liquid Chromatography
LC/IR	Liquid Chromatography/Infrared Spectroscopy
LC/LLE/IR	Liquid Chromatography/Liquid–liquid Extraction/Infrared
LC/MS	Liquid Chromatography/Mass Spectrometry
LC/PB/IR	Liquid Chromatography/Particle Beam/Infrared
LLE	Liquid–liquid Extraction
MALDI	Matrix-assisted Laser Desorption/Ionization
MS	Mass Spectrometry
NMR	Nuclear Magnetic Resonance
NPLC	Normal-phase Liquid Chromatography
PB	Particle Beam
PB/IR	Particle Beam/Infrared
R/A	Reflection/Absorption
RPLC	Reversed-phase Liquid Chromatography
RPLC/FTIR	Reversed-phase Liquid Chromatography/Fourier Transform Infrared
RPLC/IR	Reversed-phase Liquid Chromatography/Infrared
SEC	Size-exclusion Chromatography
S/N	Signal-to-noise ratio
SPE	Solid-phase Extraction
SS	Stainless Steel
THF	Tetrahydrofuran
TSP	Thermospray
UV/VIS	Ultraviolet/Visible
WN	Wire Net
ZDV	Zero-dead-volume

The essential features of an infrared (IR) microscope accessory include

1. *reflective optics for focusing, collecting, and imaging transmitted or reflected IR radiation from the sample onto a detector,*
2. *one or more variable apertures located in an image plane of the sample which serve to define the area to be recorded, and*
3. *a visible light path which is parfocal and collinear with the IR light path so that the sample can be viewed and positioned.*

The accessory is coupled to a Fourier transform IR (FTIR) spectrometer by a set of transfer optics from the interferometer into the microscope.

IR microspectroscopy provides the analyst with the capability to perform IR transmission, absorption-reflection, specular reflection, and diffuse reflection experiments on microscopic samples. Using special microscope objectives or accessories, attenuated total reflection (ATR) and grazing angle reflection experiments can be performed as well. IR microspectroscopy can also be used to map a sample's heterogeneity using a motorized stage in conjunction with a standard mercury cadmium telluride (MCT) detector. Alternatively, spatial and spectral information can be collected simultaneously using a step-scan interferometer coupled with an IR microscope and a focal plane array (FPA) detector. In either case, the superior contrast attained by functional group imaging and the selectivity found in the mid-IR region has been shown to be a powerful analytical tool.

However, diffraction ultimately limits the quality of the spectral information obtained using the IR microscope, and its effects may include poor spatial resolution, a reduction in photometric accuracy, and unreliable band intensities. Furthermore, unwanted optical effects from microscopic samples can also affect the quality of the spectrum, and sample preparation techniques must often take into account a sample's thickness, diameter, refractive index, and shape.

1 INTRODUCTION

1.1 History

IR microspectroscopy is the coupling of a microscope with an IR spectrometer for the purpose of obtaining spectra on microscopic samples. A mid-IR reflective microscope was first reported in 1949 at Oxford, England in H.W. Thompson's laboratory, and, soon after, the first commercially available IR microscope accessory was manufactured by the Perkin-Elmer Corporation.[1,2] Early investigators were interested in medical and biological applications and recorded spectra of single fibers, tissue sections, and blood smears.[3] But high-quality spectra were difficult to obtain on dispersive IR spectrometers

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

owing to the high energy losses of the microscope. Consequently, the technique remained little used until the development of FTIR spectrometers with their inherent throughput, multiplex, and frequency precision advantages. IR microspectroscopy consequently regained popularity, and a mid-IR microscope designed for the FTIR spectrometer was introduced at the 1983 Pittsburgh Conference and Exposition by Digilab Corporation.[4,5] Two years later the first symposium on the ''Design, Sample Handling, and Applications of Infrared Microscopes'' was held at a meeting sponsored by the American Society for Testing and Materials (ASTM) Committee on Molecular Spectroscopy and the Federation of Analytical Chemistry and Spectroscopy Societies; nine papers presented there were written, peer-reviewed, and published.[6]

1.2 Rationale

Not only does the IR microscope accessory provide the analyst with the capability to obtain IR spectra on extremely small samples, it is a versatile accessory which can used for transmission, absorption-reflection, specular reflection, and diffuse reflection experiments.[7,8,9] With special microscope objectives or accessories, attenuated total internal reflection and grazing angle reflection experiments can also be performed. Consequently, the technique allows for a wide variety of samples to be studied, and the reflection experiments, in general, offer ways to sample both microscopic and macroscopic samples with little or no preparation. Another important use of IR microspectroscopy is that the molecular heterogeneity of samples can be imaged and mapped.[10,11]

However, IR microspectroscopy offers a number of challenges in regard to instrumental design and sampling.[12,13] Diffraction ultimately limits the spatial resolution which can be obtained using the IR microscope, and unwanted optical effects from microscopic samples can affect the quality of the spectrum.[14]

Finally, owing to the selectivity of molecular information which can be attained, the vast number of applications of IR microspectroscopy found in the literature have been in the mid-IR region. The review will therefore focus primarily on the instrumental methods of mid-IR microspectroscopy in the wavelength range from 2 to 20 μm, including how one minimizes the effects of diffraction, refraction, reflection, and absorption by sampling techniques or instrumental parameters. However, near-infrared (NIR) microspectroscopy is an emerging field with distinct advantages in regard to some sampling factors and instrumental design considerations, and these aspects will be addressed as well. For all the apparent advantages of NIR microspectroscopy which will be mentioned, the facts remain that both the inherent functional group contrast needed for NIR imaging and the selectivity which allows for material identification are highly limited.[15] IR microspectroscopy in the mid-IR range is generally far superior and more widely applicable.

2 THEORETICAL CONSIDERATIONS IN INSTRUMENT DESIGN

2.1 Diffraction

Diffraction plays a major role in microspectroscopy when the sample size is on the order of the wavelength of light being used according to Rayleigh's relationship described in Equation (1):

$$D = \frac{1.22\lambda}{\mathrm{NA}} \tag{1}$$

where D is the diameter of the object and λ is the wavelength of light. NA is the numerical aperture which is a measure of the collection ability of an optical system.[7]

The effects of diffraction are graphically illustrated in Figure 1 which shows the diffraction pattern, or Airy disk, which results when a 17 μm IR point source is imaged by an optical system with a NA of 0.58, a typical NA for an IR microscope objective. (17 μm is the longest wavelength in the mid-IR range detected by a narrow-band MCT detector.) Notice that the energy is not imaged to a point but appears as a succession of bright rings which contain some of the energy from the original source. For the experimental conditions described, there will be 85% of

Figure 1 Graphical representation of an Airy disk for a 17 μm point source focused by an optical system with a 0.58 NA. The dimensions given are the outer diameters of the bright rings.

Figure 2 (a) Spectra of a cellulose acetate film recorded within a 8 mm × 240 mm diameter aperture, (b) recorded with the film's edge aligned with the edge of aperture image, and (c) recorded with the film's edge 40 μm away from the aperture's edge. (Reproduced by permission of the Society for Applied Spectroscopy from A.J. Sommer, J.E. Katon, *Appl. Spectrosc.*, **45**(10), 1633 (1991).)

the total original energy in the central spot, which is 36 μm in diameter as calculated by Equation (1). The rest is distributed among the remaining rings, and 5% of the energy still remains beyond the outer diameter of the fourth ring at 124 μm. Likewise, the IR radiation collected from a 17 μm diameter sample will result in a "blurring" of spectral information.[13] The energy which reaches the detector will primarily contain information about the sample, but like the fringes of the Airy disk, radiation which is present outside areas defined by the aperture, called spurious energy, can also reach the detector. Studies show that using a 8 μm effective diameter aperture results in an actual sampling diameter of 48 μm, for example, while using a 24 μm aperture results in a sampling diameter of 56 μm.[14] Diffraction effects can occur at either the high-contrast apertures located in the image plane(s) of the sample which are used to delineate the area or at the sample itself. Some of these effects can be addressed through sampling considerations and will be discussed in section 4.1.

First consider diffraction at the aperture. If an absorbing sample is nearby or adjacent to the sample under study, the spurious energy may result in absorption bands from the neighboring object "contaminating" the IR spectrum of the sample. The spatial resolution of the IR microscope is effectively decreased, and the two objects are not resolved. This is illustrated in Figure 2 which shows spectra of a cellulose acetate film obtained using a 8 mm × 240 mm aperture when the film completely fills the entire aperture (Figure 2a), when the edge of the film, out of view, is lined up with the edge of the aperture (Figure 2b), and after the edge of the film has been moved 40 μm away from the edge of aperture image (Figure 2c). Although there was no sample in the field of view defined by the aperture in the middle and bottom spectrum, spectral contamination is clearly present from the cellulose acetate even from 40 μm away, a situation with important implications for the analysis of multilayered polymer cross-sections.[7,14]

If there is only a nearby hole, that is if the free-standing particle is well removed from any other sample, the stray light reaching the detector may result in an offset of zero percent transmission. The photometric accuracy is decreased, and quantitative measurements are affected.

One way to minimize the above diffraction effects is to use dual remote (confocal) aperturing where an aperture is placed in an image plane located both before and after the sample. For example, Figure 3 shows the IR

Figure 3 IR spectra of a hair fiber collected with a single aperture placed before the sample, A, a single aperture placed after the sample, B, and with both apertures in place, C. (Reproduced by permission of Marcel Dekker, Inc. from J.E. Katon, A.J. Sommer, P.L. Lang, *Appl. Spectrosc. Rev.*, **25**, 173–211 (1989–1990).)

transmission spectrum obtained on a hair fiber collected with a single aperture (A and B) and with confocal apertures (C). Although the thickness of the fiber is such that the N–H stretching (3300 cm^{-1}) and the amide I and II (1650, 1550 cm^{-1}) absorptions are totally absorbing, a marked offset from zero transmission is observed for single aperture systems, while an improvement is noted for the confocal configuration.[7]

It is important to note that while the theoretical spatial resolution using standard mid-IR microscope accessories is estimated at 34 μm using the previous criteria ($17\,\mu m = \lambda$; $0.58 = NA$), microspectroscopy in the *near*-infrared region, from 1 μm to 4 μm, offers the potential for higher spatial resolution in accordance with Rayleigh's criterion.

2.2 Numerical Aperture

Another variable in IR microspectroscopy which may be altered to our benefit is the NA. NA, is defined by Equation (2):

$$NA = n_1 \sin\theta \tag{2}$$

where n_1 is the refractive index of the medium and θ, is the half angle of collection.[13] Figure 4 illustrates the how NA increases with collection angle.

Increasing the NA of the focusing lens and collecting objective will decrease the beam diameter as well as the distance needed to spatially resolve two closely spaced samples as Equation (1) predicts. It also increases the throughput, Θ, which is the product of the solid angle subtended by the objective and the area of the focused beam, A. According to Messerschmidt[13] the throughput is related to NA by Equation (3):

$$\Theta = 2\pi[1 - (1 - (NA)^2)^{1/2}]A \tag{3}$$

Therefore one could design a microscope of high NA which would allow the use of dual aperturing to reject stray light while at the same time keep an adequate energy signal. Equation (3) predicts that for a system of 0.50 NA there is about five times more signal than for a 0.25 NA system.[13] In addition, Messerschmidt has shown that the 95% confidence level for the spurious energy rejection occurs at a two-wavelength-wide slit width for a dual aperture system with a 0.50 NA versus at a four-wavelength-wide slit for a system with a 0.25 NA. Therefore, a dual-masked system of 0.50 NA can analyze samples two times smaller than a single-masked system of 0.25 NA with an equivalent level of spurious energy rejection and with an increase in signal by a factor of five.

Figure 4 The relationship of NA to collection angle.

As the NA of the lens increases, on the other hand, the working distance decreases.[13] An adequate working distance is necessary for mounting cells and special stages and is therefore an important consideration in transmission experiments. For example, a 0.65 NA lens with 32 × magnification has an 8 mm working distance, while a 0.58 NA lens with 15 × magnification has a 15 mm working distance.[16] In addition, as NA increases, so do spherical aberrations which effectively limit the flatness of fields for wide-area imaging.[15] In other words, rays further from the optical axis are brought to a focus at a location nearer to the lens than those rays closer to the optical axis.

In regard to NIR microspectroscopy, a significant NA advantage can be achieved since refracting (glass) objectives can be employed. Refracting objectives, in comparison to reflective objectives which must be used in the mid-IR, can have higher NA. The use of higher NA objectives can result in an increase in both spatial resolution and throughput as described in Equations (1) and (3) respectively.[15]

2.3 Signal-to-noise Ratio

Griffiths and de Haseth state that the largest source of noise in IR spectrometry is detector noise.[5] Furthermore, the optimum performance is found when the optics are throughput-matched, a condition which exists when the detector is exactly filled by the image of the source.[5] However, in regard to IR microspectroscopy, since the sample is brought into focus and defined by a variable aperture(s), the size of the image at the detector is dependent upon the sample size. Therefore microscope accessories are not designed for the system to be throughput-matched, for in doing so it would be ideal for one specimen size only.

It is customary for microscopes to be designed, aligned, and tested with a 100 μm diameter circular pinhole as the sample. If the optics provide 1 : 1 imaging from the sample to the detector, then a 100 μm diameter image will underfill a 250 μm by 250 μm area detector. Under these conditions, a 100% transmittance line at 2200 to 2100 cm^{-1} typically produces a signal-to-noise ratio (S/N) of 4000 : 1 or greater for a 2 minute collection time using

$4\,cm^{-1}$ spectral resolution, measuring peak-to-peak noise, and with a narrow or medium band MCT detector.

3 THE INFRARED MICROSCOPE

Figure 5 shows the essential features of the standard IR microscope. They include one or more variable apertures located in the image plane of the sample which serve to define the area to be recorded and reflective optics for focusing, collecting, and imaging transmitted or reflected IR radiation from the sample onto a detector.[7] The microscope must also have a visible light path which is parfocal and collinear with the IR light path so that the sample can be easily viewed and positioned. The accessory can be coupled to an FTIR spectrometer by sending an external IR beam via a set of transfer optics from the interferometer into the microscope which is located to one side of a standard IR bench. Another type of instrumentation houses the interferometer, optics, and microscope all in one enclosure.

Figure 5 Optical diagram of a standard IR microscope accessory. (Reproduced by permission of Marcel Dekker, Inc. from J.E. Katon, A.J. Sommer, P.L. Lang, *Appl. Spectrosc. Rev.*, **25**, 173–211 (1989–1990).)

3.1 Objectives and Condensers

The objective and the condenser are the main lenses in the IR microscope accessory. Reflecting optics are typically used for these lenses in the mid-IR since they do not absorb IR light, possess chromatic aberrations, or introduce strain birefringents. Although two types can be found in IR microscopes, the on-axis Schwarzschild-type (commonly referred to as the Cassegrain) and the off-axis parabolic lens, all current models use only the Schwarzschild-type reflecting objectives. Figure 6 shows a cross-section of a typical Schwarzschild lens.

The Schwarzschild lens is used as a focusing lens, or objective, because of its high image quality and efficiency. These objectives have NAs which range from 0.28 to 0.60 and magnifications up to 36×. Although there is no dependence of magnification on signal, higher

Figure 6 The cross-section of a Cassegrainian lens. (Reproduced by permission of Marcel Dekker, Inc. from J.E. Katon, A.J. Sommer, P.L. Lang, *Appl. Spectrosc. Rev.*, **25**, 173–211 (1989–1990).)

magnification objectives can allow the use of wider apertures to define the sample and therefore reduce diffraction effects at the aperture. However, as noted above, there is also a decrease in working distance. A standard Schwarzschild lens focuses IR radiation onto the sample with light rays ranging from 12° to 35°.

Unique to the reflecting objective is the characteristic known as central obscuration which is defined as the light intensity obstructed by the secondary mirror to that which would have been received by the primary mirror in its absence. Central obscuration is typically minimized to values below 25%.[7] The obscuration has the unwanted effect of reducing image brightness by spreading the diffraction pattern. In comparison with refracting objectives, centrally obscured objectives are limited to lower magnifications and NAs.

In older microscope accessories, one might find an off-axis paraboloid serving as a condenser. But the parabolic lenses, in general, provide a poorer definition of sampling area, produce more glare, and provide a wider focal beam at the sample than the Schwarzschild condensers.[16] The consequence of a larger focal diameter is that for samples smaller than the beam, more spurious energy may be introduced.

Refraction by the sample support is an important consideration in the design of the objectives and condensers. For example, when light passes from a lower refractive index medium to a higher one, the rays are bent toward the normal. The shift, which is also dependent on thickness, t, is described by Equation (4):

$$(n - 1.0)\frac{t}{n} \tag{4}$$

where n is the refractive index of the specimen, and the refractive index of air is assumed to be 1.0.[13] In a visible light microscope the objective is designed with a correction for a standard cover glass, and the condenser, for a standard glass slide. In IR microspectroscopy, the sample might lie on a variety of supports ranging from potassium chloride or zinc sulfide, to diamond or silicon. Therefore supports which have a high refractive index or which are very thick can give rise to large focal shifts. Figure 7 demonstrates that a focal shift of about 400 μm is observed when the support is changed from potassium chloride to zinc sulfide.[7] This shift is significant considering that the typical sample thickness is usually less than 10 μm. Since the beam is not in focus at the sample, it cannot be focused adequately onto the detector, and the result is a decrease in the S/N and photometric inaccuracy. This focal shift can be compensated for by refocusing the condenser. The fixed off-axis system cannot be easily refocused and, thus, puts limitations on the type of sample supports and/or sampling cells one can use.

Figure 7 Focal shifts associated with refractive index changes. (Reproduced by permission of Marcel Dekker, Inc. from J.E. Katon, A.J. Sommer, P.L. Lang, *Appl. Spectrosc. Rev.*, **25**, 173–211 (1989–1990).)

A related phenomenon is spherical aberration, due to focal shifts which arise when an IR window is placed over the sample. Some Schwarzschild objectives contain a spherical aberration correction so that the analyst may compensate for these focal shifts.[16] These objectives can compensate for windows ranging from 1 mm to 3 mm in thickness.

3.2 Apertures

Sample definition can be obtained in two ways. One alternative is to place the sample in a pinhole.[17] However, this process is a tedious and time-consuming task. The other alternative is to place and adjust remote apertures in the sample's image planes to define the sample area as previously described and illustrated. Although the placement of an aperture at the image plane is traditionally called a field stop by microscopists, the term aperture has been employed by manufacturers of IR microscopes and will be used here. In all IR microscopes an aperture is found between the sample and the detector. Yet as stated in section 2.1, spurious energy can reach the detector owing to IR light bending around the aperture's edge. To minimize the effects from diffraction, some microscopes have an additional aperture which is positioned in an image plane located between the source and the sample. It has been found

Figure 8 The optical diagram of the Continuμm™ microscope in the transmission mode. (Reproduced by permission of Spectra-Tech, Inc.)

that the latter aperture is more important especially if the specimen plane is flooded with energy or if the specimen is highly scattering.[12,13] The latest Spectra-Tech, Inc. design uses an optical path which results in a single aperture to effectively achieve confocal aperturing as Figure 8 illustrates.

Other microscopes have apertures made of low-E glass which are transparent to visible light, but not IR radiation. Additionally, the Perkin-Elmer AutoIMAGE microscope uses ''whole field of view'' apertures which keep the sample in view when masking an area of interest. The sample area is defined on its visual image using a computer ''growbox''. But during spectral acquisition, motor-driven aperture blades automatically adjust to the dimensions defined by the user.

3.3 Stages

The IR microscope stage needs to accommodate samples, sample supports, and sampling cells of various sizes and shapes. Stages are available to facilitate sample positioning through different amounts of X, Y, and Z travel and can be operated manually or can be motorized for precise, accurate, and easy positioning of samples. Motorized stages, which can be interfaced with the IR spectrometer's data acquisition software via RS-232 communications, are used routinely for mapping the sample. Samples can be stepped as small as 1 μm increments and as precisely as $+/-0.3$ μm. For polarization studies a stage which can provide rotational travel or angular movement is often used. Finally, for the study of samples in controlled temperature environments as well as the study of phase transitions and liquid crystals, a heated/cooled stage is required. These stages incorporate a temperature-, moisture-, and light-resistant window, like diamond, for transmission studies and may provide a range of temperatures from 200 °C to 600 °C.

3.4 Visible Illumination and Viewing Systems

It is a requirement that the IR microscope accessory also function as a visible microscope so that the sample can be found, positioned, and focused. Since the visible microscope is especially important for examining the heterogeneity of a sample, IR microscopes need to allow for the observation of transparent or opaque samples. Consequently, the visible illumination systems must provide a light source below the sample for transmission viewing and a light source above the sample for viewing in reflection. Uniform illumination is critical for maintaining image quality and so Koehler illumination is standard on many microscope accessories. Koehler illumination results when the filament of the light source, a coiled tungsten wire, is imaged into the back focal plane of the objective.[16] The eyepieces for viewing can range from 5× to 20× in magnification and often contain a reticle for the measurement of sample dimensions. Trinocular or quadnocular viewers are available which allow for simultaneous photomicrography or photomicrography and video viewing, respectively.

A wide variety of refracting, transmitting glass objectives are also used for visible viewing or photomicrography, ranging from 4× to 40× in magnification, as well as phase contrast objectives which improve the visibility of colorless samples like certain polymers or unstained biological samples. Microscopes also allow for the positioning of a visible polarizer and analyzer so that various optical properties like refractive indices, angle of extinction, birefringence, and sign of elongation can be measured. Condensers are optically matched to the visible condensers and the type can vary depending on application, such as phase contrast, polarized light, or dark-field microscopy.

3.5 Infrared Sources and Detectors

The IR source used in microspectroscopy is the same as the source on all IR spectrometers, a nichrome wire or a silicon carbide material. Both emit blackbody radiation and operate in the range from 1273 K to 1573 K. However, the standard triglycine sulfate detectors are not used because their sensitivity is too low for microscopic applications. Instead, liquid-nitrogen-cooled semi-conductor detectors are used, the most common being the MCT detector. MCT detectors have different sensitivities, and the greater the sensitivity, the narrower the detection range. For example, a wide-band MCT detector has a range down to $450\,cm^{-1}$ while a narrow-band detector has a range to $580\,cm^{-1}$; however, a wide-band detector has only about 25% of the detectivity. Although MCT detectors are available with sizes ranging from $100\,\mu m \times 100\,\mu m$ up to $2\,mm \times 2\,mm$, the $250\,\mu m \times 250\,\mu m$ is standard equipment for a microscope accessory. Most detectors are housed in the microscope assembly itself.

FPA detectors are discussed in section 6.2.

3.6 Purge

Atmospheric carbon dioxide ($2350\,cm^{-1}$ and $670\,cm^{-1}$) and water ($3400\,cm^{-1}$ and $1640\,cm^{-1}$) absorptions are often present in spectra obtained through an IR microscope. Any change in the amount of these atmospheric gases from the time the background is obtained to the time the sample scan is obtained will result in positive or negative absorptions in the spectrum. An adequate purge must be provided for the IR microscope accessory if a spectrum free from atmospheric interference is to be obtained. A purge can be provided for by enclosing the microscope in plexiglass or by a series of devices: purge enclosures for seal areas below the stage, a bellows to connect the condenser to the aperture location, purge skirt for the objective, and a flexible baffle for the top of the condenser. Short optical paths are also helpful in maintaining a good purge.

However, traditional purge problems may become negligible with the availability of software which easily and accurately compensates for various amounts of unratioed atmospheric absorptions in the spectrum. Perkin-Elmer's Atmospheric Correction software, for example, models the absorption bands from water vapor and carbon dioxide and removes them via a mathematical treatment which not only takes into account the amount of water or carbon dioxide, but subtle band shifts which may arise.

3.7 Automation

At present, most "standard" IR microscopes are fully automated. For example, aperturing is performed interactively with motor-driven aperture blades and focusing achieved with the one touch of a computer button. There is automatic adjustment of microscope configuration between visible viewing and the IR collection mode, as well as from the IR reflection mode to the IR transmission mode. The degree of visible illumination, the position of the Cassegrainian condenser, and the visible magnification can be adjusted through computer control rather than performed manually at the microscope. Furthermore, the motorized stage has become standard equipment and is often used as a multi-sampling device in addition to mapping. Several free-standing samples are placed on the stage, their coordinates programmed into the software, and the microscope is left to find, focus, and record spectra on the individual samples.

4 BASIC TRANSMISSION TECHNIQUES AND PRINCIPLES

A common experiment performed in IR spectroscopy is the transmission experiment, the measurement of the IR radiation which has been transmitted through a sample. This experiment is performed using the IR microscope as the ray traces in Figure 1 and Figure 8 illustrate. The success of the transmission experiment, that is, the quality of the resulting spectrum, is very dependent upon sample preparation. This is because, by virtue of the microscopic sample's size, it is essentially an optical element of the microscope.

4.1 Sampling Considerations

The ideal sample for transmission microspectroscopy is one that does little to disrupt the optical path of the IR radiation. The requirement for such a sample would be an appropriate path length so as not to produce totally absorbing bands in the spectrum, a large enough diameter so that diffraction effects are minimized, and a smooth

contour so that no scattering takes place. Consequently, any preparation of the sample serves to address one or more of this issues.[9]

In macroscopic sampling, we rarely run a transmission spectrum on an undiluted sample with the exception of a thin film. The same consideration must be given to most microscopic samples; they are often too thick to obtain high-quality transmission IR spectra without reducing their path length. Using macroscopic methods, for example, any bands which possess total absorption that result from a thick sample would be readily apparent in the spectra since their transmittance is 0%. When using an IR microscope, however, total absorption may be offset by stray light effects as the spectrum of the hair fiber in Figure 3 shows. On other samples, the effects may be more subtle, and the broad, undefined bands which result may interfere with sample characterization. If one considers that, typically, a transmittance spectrum obtained on a 10-μm thick organic sample needs little or no ordinate expansion, then samples thicker than this will require dilution or path length reduction.[5]

Reducing the path length of a microscopic solid sample can be performed by flattening the sample with a probe tip or stainless steel bearing mounted on an axle handle (called a roller) or by placing the sample in a specially designed pressure cell with IR transparent windows. A common cell used for this is the low-pressure diamond anvil cell whose diamond absorptions occur at 1900–2100 cm^{-1}, a region where few other materials absorb.[18] In fact, IR microscopists have found it convenient to use for flattening most samples because the cell contains the sample while flattening. Often several samples are placed on the diamond cell, flattened, and then the top diamond is removed after which the spectrum is recorded on each subsequent sample. If used in this fashion, the condenser of the microscope must be adjusted to compensate for the high refractive index of the diamond as discussed in section 3.1. If the sample is fairly elastic, pressure must be maintained to keep an adequate path length, so the spectrum must be recorded while the sample is held in place in the pressure cell. In this case, both the condenser and the objective must be adjusted so that signal is not lost owing to refraction effects. When crystalline orientation or morphology need to remain unaltered, slicing the sample to achieve path length reduction may be a better alternative. Although this can be performed by hand using a razor blade, diamond knife, or other sharp device, a microtome can be used to obtain sections of reproducible thickness.[16]

Path-length concerns in the NIR region, however, are less of a problem. Since most NIR bands are a result of overtones or combinations, they are typically much weaker than their corresponding fundamental transitions, and NIR spectra can be recorded on undiluted or unaltered samples as thick as about 0.5 mm.[19,20]

Fortunately, the sampling technique of flattening to reduce path length will also help to minimize diffraction occurring at the sample's edge as well as at the apertures which are used to define the sample. Figure 9 which compares the spectrum of the cellulose acetate *film* (Figure 9b) with the spectrum of a 15 μm × 15 μm *slice* of cellulose acetate (Figure 9a) illustrates the effect of sample diffraction.[21] Both samples are the same thickness, and their spectra were obtained with an identical single remote aperture as previously discussed in section 2.1. Since the film is much larger in area than the area defined by the aperture, the effects from diffraction around the film's edges are not observed. When the spectrum of the film is compared to the spectrum of the slice, one observes that the carbonyl stretch at about 1750 cm^{-1} has a peak intensity of 28% T versus 36% T, and the C–O stretch at about 1225 cm^{-1} has an intensity of 18% T versus 38% T, respectively. IR radiation which has bent around the slice of cellulose acetate has reached the detector, and this spurious radiation is worse at longer wavelengths in accordance with the diffraction theory described in Equation (1). Varying changes in the *relative* intensities are also a result of diffraction. Compare the relative intensity of the methyl bend at 1375 cm^{-1} with the C–O stretch at 1225 cm^{-1}. The relative intensity is about the same in the spectrum of the cellulose acetate slice, while the 1225 cm^{-1} band is much more intense in the spectrum of the film. The longer wavelength band (1225 cm^{-1}) is bent around the sample more in the spectrum of the slice owing to diffraction, and the result is an increase in % T. Other studies clearly show that band intensity ratios change significantly as sample size gets smaller. However, distortions in band *shapes* can result from effects other than diffraction. The asymmetric bands observed in the middle and bottom spectra of Figure 2, for instance, appear to be the result of specular reflections off the side of the microscopic sample.[14]

As discussed in section 2.1, diffraction can occur at the aperture edges or the sample edges. One effect of diffraction around the aperture is a baseline distortion with a loss of transmission at the longer wavelengths.[22] Figure 10 shows that as the aperture becomes smaller, more energy is lost.[23] However, this baseline slope can be ratioed out of the spectrum by using the same aperture settings in the acquisition of the background spectrum as used in the sample spectrum. This is achieved by closing the aperture(s) down around the image of the sample particulate or area of interest, acquiring a single-beam spectrum of the sample, I, then moving the stage to a vacant area of the IR window without resetting the apertures. The single-beam spectrum of the window is acquired, I_0, and the two spectra are ratioed, I/I_0.

Figure 9 (a) IR spectrum of a 15 μm by 15 μm cellulose acetate slice, and (b) a cellulose acetate film. (Reproduced by permission of Plenum Press from P. Lang, A.J. Sommer, J.E. Katon, 'Infrared and Raman Microspectroscopy: An Overview of Their Use in the Identification of Microscopic Particulates', in: *Particles on Surfaces 2, Detection, Adhesion and Removal*, ed. K.L. Mittal, Plenum Press, New York, 143–161, 1988.)

Another sampling consideration familiar to IR spectroscopists is that caused by the scattering of IR radiation. An opaque, finely powdered sample or one which is rough on a microscopic scale will scatter the light, and the scattering is proportional to the square of the difference in the refractive index of the sample and the surrounding medium.[24] Since the scattering is more marked at shorter wavelengths, the result is that the spectrum of the sample exhibits a sloping baseline. The common correction for macro samples is to suspend them in a medium which has a similar refractive index and coalescing the two into a pellet. KBr, KI, CsBr, CsI, for example, are commonly used media. In microspectroscopy such a ''pellet'' may be formed by placing one or two salt crystals in the sample and pressing down with a pointed probe while rolling it and applying pressure. If the probe has an area of 25 μm × 25 μm, 0.1 pounds of force on the handle becomes translated into about 100 000 lbs in^{-2} at the probe tip, well enough for an adequate pellet.[25] In addition, the sample area is increased along with the concomitant increase in aperture size, thereby minimizing diffraction effects; the signal is increased with a resulting increase in S/N; and the sample is diluted, and thus total absorptions are less likely. Other investigators have found that scattering by opaque particles can be reduced by pressing them directly into KBr windows or suspending them in Nujol.[26,16]

However, some workers still think the use of the diamond anvil superior. The sample preparation is simpler, and problems related to baseline slope from inadequately ground KBr are omitted, in addition to water adsorption on KBr which might prevent accurate hydroxyl group assignments.[27]

4.2 Detection Limit

The eye can detect objects which are below the diffraction limit of visible light, although it may not resolve two objects which are close together.[7] Therefore, diffraction does not necessarily limit the detection of a compound in IR microspectroscopy. However, as sample size

Figure 10 The effect of diffraction caused by small apertures. Spectra A to F correspond to spectra obtained using 29, 25, 21, 17, 12.5, and 8.3 mm (actual) diameter apertures, respectively. (Reproduced by permission of Royal Society of Chemistry from P.H. Turner, *Anal. Proc.*, **23**, 268, 1986.)

approaches the diffraction limit, the quality of the spectrum decreases owing to the loss of energy, and it may be so severe that the absorptions cannot be distinguished from the baseline.

In terms of the detection of small amounts, it depends on the sample's shape, diameter, thickness, and absorption coefficient. Katon has obtained a high-quality transmittance spectrum on an approximate 6-ng particle of isotactic polypropylene, yet the sample was relatively smooth, approximately 10 μm thick and 25 μm wide. The thickness was optimum for a transmission experiment without any ordinate expansion, and the sample was large enough (and consequently the apertures) to not cause any significant diffraction effects.[25]

More impressive is the report of the absorbance IR spectrum of a single, 7-μm diameter red blood cell by Dong and co-workers.[28] Assuming the red cell has a cylindrical shape with a height of 5 μm (probably an overestimation, since red cells are characteristically concave) and an average density of 1.054 g mL^{-1},[29] the experiment indicates a detection limit (DL) of 0.20 ng of material.

Other work has shown that transmission IR microspectroscopy is suitable for the detection of 3.6-nm to 36-nm *thin* organic layers on chalcogenide fibers.[30,31] However, the authors have taken advantage of a sensitivity enhancement which results from the geometrical effects of the cylindrical fiber which serve to concentrate the transmitted radiation from the organic layer and thereby improve the S/N.

5 BASIC REFLECTION TECHNIQUES AND PRINCIPLES

In an IR microscope's reflection collection mode, a split mirror (beamsplitter) is placed in the IR beam to allow 50% of the incident light to be delivered to the objective and focused onto the sample. The light reflected from the sample is collected by the same objective and reflected by the split mirror onto the detector. This is illustrated in Figure 5 and more explicitly illustrated in Figure 11. Depending on the nature of the sample, the analyst can perform three basic experiments when the microscope is in the reflection collection mode: specular reflection, diffuse reflection, and absorption-reflection. Specialized objectives can be installed to perform other reflection experiments, such as, ATR and grazing angle reflection.

5.1 Specular Reflection

Specular reflection occurs when the IR radiation is reflected from the front surface of an optically thick dielectric sample, and the angle of the reflected light is equivalent to the angle of incident light as Figure 12 shows. Although radiation could also be refracted and transmitted, this component is not collected. Back surface reflection could also take place, but if the sample is of the proper thickness, this component will not contribute significantly. In specular reflectance Fresnel's relations apply to the process as Equations (5) and (6) describe:

$$r = \left| \frac{\hat{\eta} - 1}{\hat{\eta} + 1} \right|^2 \tag{5}$$

$$\hat{\eta} = n + ik \tag{6}$$

where r is the reflection coefficient, n is the refractive index, $\hat{\eta}$ is the complex refractive index and k is the extinction coefficient.[32] Since the specular reflectance spectrum is the plot of r versus frequency, and since the reflection coefficient follows the complex refractive index, the specular reflectance spectrum will feature discontinuity in the region of the absorption bands. These first-derivative-like spectral features, or restrahlen bands, can be observed in the top spectrum in Figure 13, a spectrum of a Nylon tie (used to fasten tubing to laboratory glassware).

A mathematical relationship known as the Kramers–Kronig integration can transform specular reflectance spectra into absorbance spectra by calculating k, n, and the phase angle shift, θ (ν).[33,34] The conventional IR absorption spectrum is then the dispersion of k, a plot

Figure 12 Illustration of specular reflection, diffuse reflection, and absorption-reflection.

of k versus frequency. The bottom spectrum in Figure 13 shows the transformed spectrum of the Nylon tie. The large negative feature at about 3600 cm^{-1} is an anomaly and indicates that the sample was not a perfect specular reflector. In fact, although the sample was optically thick, it was not completely smooth, and one could observe a visible grain in the sample which effected diffuse, random reflections. Although not in this spectrum, another common anomaly that might occur is when unratioed carbon dioxide or water vapor absorptions remain in the specular reflectance spectrum. Those absorption bands will be distorted after the KK transformation since the mathematical treatment presumes all bands result from specular reflection.

Sample preparation for this type of experiment is minimal. A sample is usually placed on top of a microscope slide and placed on the stage of the microscope accessory. The sample area is then defined by the use of one or more remote apertures, and the spectrum acquired. The background spectrum is obtained on a smooth, highly reflective, nonabsorbing surface such as a front-coated gold mirror using the same aperture setting. (This was how the spectra shown in Figure 13 were acquired.) Another sampling method suitable for the study of minerals is to embed the sample in an epoxy resin and polish the surface.[35] Regardless, specular reflection is a low-efficiency process, and therefore the largest sample area possible should be used so that an adequate S/N is obtained.

5.2 Diffuse Reflection

When an absorbing sample is dispersed in a nonabsorbing media, the incident radiation is transmitted through sample particulates and is diffusely reflected off the nonabsorbing particulates, such as ground KBr, as illustrated in Figure 12. This is the diffuse reflection experiment, and it can also be performed with a standard Schartzschild lens in the reflection collection mode. The diffuse reflectance spectrum, R'_∞, is defined as the ratio of the single-beam diffuse reflectance spectrum of the sample to that of a nonabsorbing standard. The Kubelka–Munk theory indicates a linear relationship between the diffuse reflection function, $f(R'_\infty)$ and the sample concentration, c, according to Equations (7) and (8):

$$R'_\infty = \frac{R'_\infty(\text{sample})}{R'_\infty(\text{std})} \tag{7}$$

$$f(R'_\infty) = \frac{(1 - R'_\infty)^2}{2R'_\infty} = \frac{c}{k} \tag{8}$$

where $k = s/(2.30\varepsilon)$, s is the scattering coefficient, and ε is the molar absorptivity. Therefore, one would expect the spectrum, $f(R'_\infty)$ to be similar to an absorbance spectrum as Figure 14(a) shows. After the calculation of the Kubelka–Munk spectrum shown in Figure 14(b), however, the corrected relative intensities are more similar to that of an absorbance spectrum.

Diffuse reflection can vary a great deal with particle size. To minimize this effect, uniform KCl particles which range between 75 μm and 90 μm are recommended because they show little variation in reflectance over the mid-IR region from 2 μm to 20 μm. Another caveat is that if the sample is too concentrated or undiluted, specular reflections may greatly contribute to the spectrum, resulting in the restrahlen features discussed in the previous section. Finally, since microscope optics are not maximized for diffuse reflectance experiments, one needs to obtain the spectrum using the widest apertures possible, in order to maximize energy and consequently S/N.

A typical sample preparation for the microscope accessory is to roughen the surface of the sample with a fine grit emery paper or diamond abrasive paper with the appropriate particle size. The spectrum of the ground sample left on the paper is obtained and ratioed against a spectrum of unused emery paper at the same aperture settings. (This was how the spectra shown in Figure 14 were obtained.) Alternatively, the roughened surface of the actual sample could be analyzed. Diffuse reflectance spectra of dyes separated by thin-layer chromatography have been obtained using the IR microscope.[36]

5.3 Absorption/Reflection

If a sample of the proper thickness is in intimate contact with a reflective surface, a absorption-reflection experiment can be performed when the microscope is in

the reflection collection mode. As illustrated in Figure 12, the incident light passes through the sample, is reflected off the surface, and passes back through the sample again before collection. Since absorption-reflection is approximately a double-pass transmission experiment, the maximum sample thickness is estimated at about half that for the sample measured in transmission. Given that the Schwarzschild objective delivers light at an average incident angle of 25° from the normal, the sample thickness which yields a spectrum with little or no ordinate expansion is estimated at 4.5 μm according to Equation (9):

$$2d = 10 \cos \alpha \tag{9}$$

where α is the angle of incidence and d is the thickness of the film.[5] Although light also reflects at the front surface of the sample, this contribution to the overall reflection will vary depending upon the sample's properties. If the contribution is large, restrahlen bands will be observed. Ideal samples for absorption-reflection experiments are also relatively smooth and flat, and typically tend to be coatings, films, or film-like deposits on metal.

Special objectives can be added to the IR microscope which will deliver the incident light at grazing angles, typically at a range from 65° to 85° as Figure 15 shows. According to Equation (9), measurement at a grazing angle can allow for the analysis of extremely thin films on reflective surfaces of 1 μm or less. The microscope objective offers the capability to obtain spectra on samples microscopic in dimensions in which the nominal area is approximately 50 μm × 50 μm. The Spectra-Tech grazing angle objective, for example, has 30× magnification, a NA which ranges from 0.996 at 85° to 0.51 at 33°, a working distance of 1 mm, a viewing mode, and an option for an IR polarizer. It is important to note that Pepper has found that the grazing angle objective is suitable for quantitative measurements; that is, there is effectively no angular dependence on the incident light intensity.[37]

Pepper, 'Characterization and Application of a Grazing Angle Objective for Quantitative Infrared Reflection Microspectroscopy', *Appl. Spectrosc.*, **49**(3), 354–360 (1995).)

5.4 Attenuated Total Reflection

A more widely applicable technique for IR microspectroscopy is ATR. To perform this experiment, a special objective can be added to the IR microscope which contains an internal reflection element of relatively high refractive index as Figure 16 shows.

Figure 16 Cross-section of an ATR objective in the viewing, contact, and IR collection mode. (Reproduced by permission of Spectra-Tech, Inc.)

When the IR radiation is introduced into the element, it can be total internally reflected if the incident angle is greater than the critical angle θ_c according to Snell's law described in Equation (10):

$$\theta_c = \sin^{-1} \left(\frac{n_1}{n_2} \right. \tag{10}$$

where n_2 is the refractive index of the element, and n_1 is that of medium with which it is in contact. Although complete internal reflection occurs at the interface between the two media, radiation does in fact penetrate into the rarer medium, and a sample placed in contact with the element may absorb this radiation at the point(s)

of reflection. In contrast to specular reflection, ATR is a very efficient technique with virtually no loss of energy except from absorption by the medium. The standing wave established at the point of reflection is called the evanescent wave and is described by Equation (11):

$$d_p = \frac{\lambda}{2\pi n_e(\sin^2\theta - n_{se}^2)^{1/2}} \quad (11)$$

d_p is the depth of penetration, λ is the wavelength, θ is the angle of incidence, n_e is the refractive index of the element, and n_{se} is the ratio of the refractive index of the sample to that of the element. Thus greater penetration depths are achieved for a particular angle of incidence by altering the internal reflection element. Internal reflection elements such as zinc selenide ($n_e = 2.4$), offer a greater penetration depth than germanium ($n_e = 4.0$), for example. At incident angles of approximately 45° and assuming 1.5 for the sample's refractive index, this corresponds to a depth of 0.2 λ and 0.066 λ, respectively, and offers the possibility to obtain spectra at the surface of a sample. However, if the sample is multilayered or lies on an absorbing substrate, the sample needs to be at least as thick as the depth of penetration, otherwise the medium under the sample will be detected. If a sample is completely transferred to the element and is thinner than the penetration depth, the spectrum of the entire sample will be obtained, not just the surface.

The ATR objective with magnification of 25× allows for sampling the surface of a microscopic sample with a nominal area of 50 μm by 50 μm. The small area of the microscope ATR element in combination with the single bounce reflection has the advantage that complete contact of the sample with the element is more easily achieved. Consequently, baseline distortions associated with the uneven, lower pressures which result from using macroscopic ATR elements are eliminated.[38] In addition, Reffner and Martoglio report another advantage.[16] In the Spectra-Tech ATR objective, which has a hemispherical shaped element, the cross-sectional area of the radiation passing through it is magnified by the refractive index of the element. Using a germanium element, for instance, a 2.50 mm diameter circular aperture in the image plane corresponds to an apparent sample diameter of 100 μm but is an actual sample diameter of 25 μm. Thus, for a germanium ATR microelement, an aperture four times larger than what is usually required for a sample can be used, reducing the diffraction problem at the aperture considerably. This magnification factor associated with micro ATR elements has been verified for samples 60 μm in diameter and larger.[38]

Another theoretical consideration is that since the sample is immersed in the internal reflection element, the spatial resolution should be increased according to Rayleigh's criterion given in Equation (1). This is because the refractive index, n_1, of the medium is increased, and therefore NA is increased according to Equation (2). However, since only half of the beam is introduced into the objective and collected by the objective when the microscope is in the reflection collection mode, the spatial resolution using an ATR element will theoretically only increase by $n_1/2$.[38]

Sample preparation is typically nonexistent using the ATR objective. The sample is brought into view and positioned using a refracting lens which is built into the middle of the ATR objective as Figure 16(a) shows. Then with the slide selector in the intermediate position, Figure 16(b), the stage is adjusted to bring the sample in contact with the internal reflection element by either visual observation or by using an automated pressure sensor. After defining the sample area to be analyzed using a remote aperture, IR radiation is then directed into the internal reflection element as Figure 16(c) illustrates, and a sample spectrum is obtained. The sample spectrum is ratioed to a background spectrum obtained while the objective is not in contact with the sample. Since spectra can be obtained so easily using a micro ATR objective, and because the ATR spectra have equivalent S/Ns as those obtained in transmission on samples of the same size, the use of ATR microspectroscopy has become more widespread.[38]

6 INFRARED IMAGING SYSTEMS

6.1 Traditional Mapping

Using a motorized stage, IR imaging can be performed with a standard MCT detector and microscope accessory in either the reflection or transmission collection mode. IR spectra can be obtained for a contiguous sample area by stepping the stage (a computer-controlled operation) in small increments which are the same as or less than the effective aperture size and recording the spectrum at each step. The corresponding mapping software then plots the intensity of an IR absorption band or absorption band ratio as a function of x-y coordinates, displaying the images as wire frame or contour plots as Figure 17 illustrates.[11] In this fashion, a particular functional group's concentration is mapped across a heterogeneous sample. One can also opt to collect spectra in a straight line across a sample as Figure 18 illustrates.[39]

The main problem associated with mapping is the long collection time. If a high-quality spectrum takes 10 s to obtain at each stage increment, then a map formed from a 64 μm × 64 μm spectral grid (4096 spectra) will take approximately 11 h to obtain. This could correspond to a 225 μm × 225 μm sample stepped across in increments of 15 μm, for example. Another problem, mentioned in section 2.1, is that owing to diffraction at the aperture(s)

Figure 17 Functional group images of a 2 mm × 2 mm serpentine sample. edge, there will spectral contamination from surrounding areas in each spectrum. However, it has been suggested that if the step size is significantly smaller than the

Figure 18 A line map of spectra obtained at 10 μm steps across a human osteonal bone sample. The spectra show that the mineral density increased as a function of increasing distance from the osteonal center ($z = 0$ μm). The spectrum was obtained by transmission on a 5-μm cross-section of a bone sample which had been embedded in polymethyl methacrylate. (Reproduced by permission of Springer-Verlag from E.P. Paschalis, E. DiCarlo, F. Betts, P. Sherman, R. Mendelsohn, A.L. Boskey, *Calcified Tissue Intl.*, **59**, 480–487 (1996).)

effective aperture size (for example, 3 μm versus 15 μm, respectively) that the effective spatial resolution can be increased if chemometric methods are employed in conjunction with mapping. Harthcock has shown that factor analysis of the data can reveal the number of spectrally different layers of a polymer laminate, even when the width of one or more polymer layers is below the diffraction limit, providing that linear additivity holds and experimental noise is within reasonable limits.[40] However, sampling will take considerably longer under these conditions.

6.2 Focal Plane Array Detectors

Spatial and spectral information can now be collected simultaneously using a step-scan interferometer coupled with an IR microscope and a FPA detector.[41] The FPA detectors consist of a grid of very small IR detectors each of which can detect radiation from different locations of the sample. Thus, at each detector element a NIR or mid-IR spectrum is obtained for each region of the sample. One can either observe the spectrum at a particular pixel which corresponds to a particular sampling region or observe the intensity of a particular absorption band for each pixel as Figure 19 shows.[42]

FPA detectors can be fabricated from a small selection of materials including platinum silicide (1.0–5.7 μm), palladium silicide (1.0–3.2 μm), iridium silicide (1.0–8.2 μm), indium antimonide (1.0–5.5 μm), indium gallium arsenide/indium phosphorus (1.0–1.7 μm), germanium (1.0–1.6 μm) and MCT (2.5–12 μm).[15] Digilab's Stingray FPA detectors, for example, are constructed of either

Figure 19 Illustration of a ''stack'' of FPA data. (Reproduced by permission of Spectroscopy from J.L. Koenig, C.M. Snively, 'Fast FTIR Imaging: Theory and Applications', *Spectrosc.*, **13**(11), 22–28 (1998).)

a 128×128 InSb element grid or a 64×64 MCT element grid for work in the NIR region or mid-IR region, respectively. Past instrumentation has been designed using an FPA detector configured with an acousto-optical tunable filter (AOTF)[43] or a tunable bandpass dielectric filter[44] which allows for selection of a wavelength which corresponds to a specific absorption band by changing the spectral bandpass. The imaging process occurs by selecting a wavelength, collecting a spectrum, and then repeating the process. The AOTF and dielectric filters are limited to the very near IR region ($10\,000–5000\,cm^{-1}$) and the NIR region ($4000–2300\,cm^{-1}$) respectively.

More recently, FPA detectors have been used with a step-scan interferometer since as many as 16 000 outputs must be read simultaneously at each retardation interval of the interferometer.[45,46,47] Standard rapid-scanning interferometers which measure the output from a single detector, scan at speeds ranging from millimeters per second to centimeters per second. Since this is too fast to obtain acceptable S/N from the less-sensitive FPA detectors, radiation must be collected over a longer time period. Consequently, at each step of the interferometer, several image frames are obtained and co-added as needed to obtain adequate S/N. Although the time required to Fourier transform and ratio to background is several minutes of processor time, the time required for the collection of 4096 spectra ($16\,cm^{-1}$ resolution, 150 co-added image frames during each 1 second interferometer step, 255 steps, 1 scan) is less than five minutes.[46]

Other than a marked decrease in the collection time of the image, the use of FPA detectors can, in theory, increase the spatial-resolution capabilities of the IR microscope. Since IR spectra are collected across an unapertured sample, there is no diffraction by the aperture. The size and number of individual detector elements in conjunction with the optical configuration define the spatial resolution.[42] For example, if a sample of $500\,\mu m \times 500\,\mu m$ dimensions is focused onto a 64×64 detector, each pixel collects information from a $7.8\,\mu m$ square region of the sample.

Although the image quality and speed are superior using FPA detection, the lower sensitivity of the FPA detectors, often results in individual spectra with lower S/N ratios than spectra obtained mapping with a single-point MCT detector. Furthermore, although it is possible to obtain spectra at spectral resolutions of $4\,cm^{-1}$ or higher using FPA detection, it is currently not practical owing to the difficulty of handling large data sets generated at higher spectral resolutions.[41]

7 PERSPECTIVE AND FUTURE DEVELOPMENTS

7.1 Spatial Resolution Below the Diffraction Limit

The relatively recent coupling of an IR microspectrometer with the IR radiation emission from the National Synchrotron Light Source has shown a significant increase in spatial resolution and S/N performance.[48,49] This result is due to the source being highly collimated and small, 200 μm by 400 μm; it is 100 to 1000 times brighter than from a 1500 K thermal emission source. Experiments have shown that using 6 μm × 6 μm dual remote apertures, the synchrotron system clearly resolved 4 μm layers in a cross-section of a multilayered laminate and provided a S/N greater than 200 : 1.[50]

Spatial resolution can also be improved through the use of pseudo near-field techniques where a small aperture is placed in contact, or nearly in contact, with the sample.[51,52] IR mapping can performed if an aperture turret is constructed to allow for x-y motorized stage movement.[52] In both cases, the aperture effectively prevents the light from spreading into a diffraction pattern. Although the technique substantially enhances the spatial resolution, it generally requires more alignment and increased data-collection times. A related, more elaborate technique is near-field optical microscopy (NFOM) where the evanescent field created by total internal reflection, the near-field, is modulated by the sub-wavelength details of a sample's surface. The modulated field is then detected by the tip of a tapered glass fiber, and an image is constructed when the tip scans the surface by a stepping device. The image is dependent upon both the topography and the sample's absorption properties. The NFOM is an important spectroscopic technique, since theoretically the size of the fiber's tip can control the lateral spatial resolution. Piednoir and Creuzet describe a photon scanning tunneling microscope adapted to perform NFOM in the IR range.[53] Their experiments suggest that with improvements in the fabrication of the probe, an increase in sensitivity can be achieved along with the concomitant improvement in spatial resolution.

7.2 The Eighth Age of Infrared Spectroscopy

In the 1973 editorial, 'The Seven Ages of an Analytical Method,' Herbert Laitinen, Editor of *Analytical Chemistry*, wrote that IR spectroscopy had reached its seventh age.[54] At this stage of analytical development, according to Laitinen, a technique was at the end of its useful life and was gradually being replaced by better analytical methods. But much to the delight of IR spectroscopists, nothing could have been further from the truth. In fact, shortly after the publication of the editorial, IR spectroscopy began to experience an age of explosive growth as a result of the development of the FTIR spectrometer. Noted vibrational spectroscopist, Dr. Bruce Chase, has introduced the idea that vibrational spectroscopy, in general, has undergone an ''Eighth Age'' of analytical development.[55] In regard to IR spectroscopy, the Eighth Age manifested itself in the development of many sophisticated sampling methods including, but not limited to, reflectance spectroscopy(s), photoacoustic spectroscopy, IR emission spectroscopy, gas chromatography linked to FTIR spectrometry, and IR microspectroscopy. Each IR sampling method has its own development that can be described by Laitinen's Ages: experimental measurements in the research lab establish validity of the method, the instrument is introduced into the general laboratory where nonspecialists perform the measurements, the method is accepted and in competition with existing methods, applications appear in a wide variety of scientific areas, and applications become standard methods. Furthermore, because IR microspectroscopy is IR spectroscopy on the microscopic level, we are not surprised that it can be further broken down into its many sampling methods (sections 4, 5, and 6) each of which has gone through a ''mini-life'' of ages. These factors, among others, account for the explosion which Chase refers to as the Eighth Age.

Real-time IR imaging is the newest IR microspectroscopic sampling technique. The validity of the method is being established, it is beginning to be introduced into the general lab, and is offering some competition to traditional mapping techniques. Future developments in *uncooled* FPA detectors for both the near- and mid-IR regions will allow for higher pixel densities, ease of accessibility, and reduced cost.[56] Thus real-time imaging using the IR microspectrometer may well become routine for many applications, including medical diagnoses and NIR quality control.

In this article, after reviewing the different mathematical methods used in quantification we will describe and discuss their respective advantages and inconveniences. First of all, different examples of applications of infrared (IR) spectroscopy, used with or without other analytical chemistry methods, will be presented. Some examples of direct quantitative analysis in food analysis will be reviewed: lipids (measurement of unsaturation degrees, lipids determination), carbohydrates, proteins (secondary structures, quantitative analysis). We will also focus on original examples of the use of IR spectroscopy combined with enzymes.

Secondly, some examples of Fourier transform infrared (FTIR) analysis coupled with other analytical methods are reviewed in the following fields: FTIR quantification in pharmaceuticals, petroleum, paints and other industrial products and in the fields of health, environment, and trace compounds analysis.

Finally, we will discuss the limitations and perspectives of IR spectroscopy for quantitative analysis. It appears that the most significant developments in the field of quantitative analysis will most probably come through progress in chemometrics and flow analysis (FA) (automation).

1 INTRODUCTION

Absorption spectrometry investigates the interactions between radiation energy and samples. The frequencies, or wavelengths, at which samples absorb radiation and the corresponding absorption intensities, are hereby recorded into a spectrum. These intensities are measured in terms of absorbance, whose values reflect the amount of radiation absorbed by the sample while the amount of radiation which travels through a sample is termed transmittance.

Since functional groups are known to absorb light at specific wavelengths, investigating absorption frequencies provides a means for elucidating chemical compositions. The constitution of an unknown sample can be investigated through the study of its wavelength/absorption spectrum. Investigating the chemical composition of unknown samples in spectrometry is commonly termed qualitative analysis.

It is sometimes useful to go beyond qualitative analysis when one is concerned with the amount of a constituent in a sample. This is commonly known as quantitative analysis.

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

The intensity of an absorption band is linked to the concentration of its associated constituents in a sample. A calibration model links changes in the concentration of the constituent to variations in absorbance. As a matter of fact, calibration models can be successfully used for the quantitative analysis of constituents in samples.

Near infrared (NIR) extends immediately after visible red light, from 700 nanometers (nm) to 2500 nm or, when expressed in cm^{-1}, from 14 285 to 4000 cm^{-1}. NIR spectroscopy is the most commonly used method for quantitative analysis of major biochemical constituents in food industry. The diversity of products that are analyzed by NIR is increasing.[1–4]

To date, fewer studies are concerned with quantitative analysis in the mid-infrared (MIR) range.[5–14] However, more and more papers are now reporting the use of MIR. Several reasons can be put forward to explain this recent interest in this IR domain for quantitative analysis:

- MIR spectra are complex and each functional group contributes to the spectra, which results in numerous bands overlapping.
- Water is a major constituent in biological products and strongly absorbs MIR radiation.
- IR radiation weakly penetrates solid samples. As a consequence, this method only investigates samples' surfaces.
- With classical systems such as pellets or liquid cells employed to obtain MIR spectra, problems are encountered and it is difficult to establish the band-pass correctly or to clean and mount these systems.

However, the advent of FTIR spectroscopy, coupled with the use of powerful computers and the advent of new techniques such as FA and attenuated total reflectance (ATR), have considerably promoted the use of MIR spectroscopy.

Figure 1 shows the evolution of the scientific literature on quantitative analysis by IR spectrometry and, as can be seen, we are nowadays at the beginning of a new era of quantitative IR.

The use of computers has revolutionized studies in many aspects of biological sciences. Data analysis is a relatively new technique which only became popular from the 1960s onwards. The need for data analysis emerged from scientific disciplines, like physics or analytical physical chemistry, where workers had to manipulate considerable amounts of data. At the same time the computer appeared. It was thereby possible to process a considerable amount of data with great speed.

Data analysis is useful for investigations in which numerous variables occur; the terms multivariate analysis or multi-criterion analysis are used. These call upon mathematical spaces containing *n* dimensions. However, for a long time computers have remained for a long time the privilege of specialists. The advent of more and more powerful microcomputers has allowed the introduction of these multidimensional analyses into research laboratories.

Statistical data analysis has been applied to IR spectral data only recently with the advent of Fourier transformed spectrometry in the late 1970s. It follows that this IR technology particularly generated the ideal data required by these statistical methods.

Figure 1 Evolution of the scientific literature on quantitative analysis by IR spectroscopy.

Several mathematical methods can be used for processing IR spectral data in the context of qualitative or quantitative analysis.

In this article, we will first review the different mathematical methods used in quantification and discuss their advantages and inconveniences. We will then describe different example applications of IR spectroscopy used with or without other analytical chemistry methods for the analysis of foods, pharmaceuticals, petroleum products, paints, etc. Original examples of the use of IR spectroscopy combined with the use of enzymes will be also presented. The future prospects of this technique will be discussed.

2 QUANTIFICATION METHODS

In this section, we will describe the most commonly used mathematical methods in IR-based quantitative analysis. Some methods are univariate (solve only one equation based on one measured value and have one calibration value per sample), whereas others are multivariate (solve a series of equations using many measurements per sample for one calibration value). Duckworth[15] has extensively reviewed these methods.

2.1 Selection of the Analysis Region

The choice of the spectral region which correlates best to the concentrations of the constituents to be predicted is one of the most delicate steps in the elaboration of the method of quantitative analysis. Generally, candidate wavelengths or spectral regions are initially chosen among those that are attributed to a constituent. This selection is usually subsequently refined through an iterative process.

The mathematical model that is then used for calculating the concentrations of constituents in unknown samples in quantitative analysis methods is the one determined by the calibration.

2.2 Classical Quantification Methods

2.2.1 Application of the Beer–Lambert Law

The principle of quantitative analysis is that intensities of absorption peaks (absorbance units) are correlated to the amount of constituents. The Beer–Lambert relationship shows that not only are the peak intensities linked to the samples concentrations but that there is also a linear relationship between them, as indicated by Equation (1):

$$A = \varepsilon cl \tag{1}$$

where A is the absorbance, ε the molecular extinction coefficient ($\text{mole}^{-1}\,\text{L}\,\text{cm}^{-1}$), c the concentration ($\text{mole}\,\text{L}^{-1}$) and l the width of the sample (cm) or the bandpass of the cell.

The intensity of an nonoverlapped characteristic absorption band of a compound is hence a function of the concentration of this compound. A calibration model links changes in concentrations to changes in absorbance through the existence of a characteristic constant (the molecular extinction coefficient) and taking into account the bandpass (l).

In cases of substances that do not interact, only one calibration standard is necessary to calculate with precision their concentrations in an unknown sample.

For samples with broad concentration ranges, the calibration is performed on several standards with varying concentrations of the quantified constituent. Spectra of standards are measured so as to determine the absorbance values at each characteristic peak.

In the simplest case, a linear calibration model is obtained: this is the calibration curve. The concentration of an unknown sample can then be easily derived from its absorbance values.

The most commonly used method for calculating a calibration equation is multilinear regression. To calculate calibration equations, several other methods have been developed: least squares regression model, classical least squares model (CLS) and inverse least squares (ILS) model, both using simple or weighed factors.

2.2.2 Multiple Linear Regression

The use of multiple linear regression for determining calibration equations is now well established, as described by several authors. When the data to be predicted are quantitative, the prediction is performed using multilinear regression equations that link calibration data to spectral data. Honigs[16] and Osborne and Fearn[2] have extensively reviewed the use of this method in IR spectroscopy.

The basic principles are summarized below:

The simplest equation that can be established is of the type of Equation (2), where C is the concentration to be predicted, A_l is the absorbance at wavelength l, and a_0 and a_1 are the regression coefficients:

$$C = a_0 + a_1 A_l \tag{2}$$

The wavelength l should be chosen in order to best predict the concentration C.

However, equations of the type of Equation (2) are only applicable for predicting the concentration of one constituent per sample. They would not be convenient for predicting concentrations of other constituents in a mixture where interactions between constituents that absorb at similar wavelength were not taken into account.

In order to take into account these interactions, multilinear regression has been introduced, which is useful for the determination of the concentration of several compounds.

The equation to be used is then as Equation (3):

$$C_j = a_{0j} + a_{1j}A_1 + a_{2j}A_2 + \cdots + a_{nj}A_n \qquad (3)$$

where C_j is the concentration of each one of the compounds to be determined, A_1 are the absorbance values measured at wavelengths from 1 to n, and a_{ij} are the regression coefficients corresponding to each compound j, from 0 to n.

This equation is known as a calibration equation or prediction equation. The absorbances A_1 are the predictive variables and C_j is the predicted variable. The coefficients a_i can be positive or negative terms and can account for interactions between constituents.

Wavelength selection is the main problem in spectroscopic analysis, and wavelength values must be selected in order to be the ones most characteristic of the compounds to be determined and to provide noninterfered data for the compounds. Additionally, in the case of IR analysis, it is necessary to establish an appropriate baseline for the IR spectrum, which could minimize the band overlapping.

The establishment of prediction equations is generally a step-by-step process. The wavelengths are selected as a function of their predictive ability. There are large absorption bands in IR spectra and the data are strongly correlated between them. Wavelength selection is actually not an easy task: replacing a spectral data point by an adjacent one may have no effect on the prediction equation.

To reduce this inconvenience, several prediction equations are retained and tested. The most predictive equation is experimentally determined by testing validation samples.

Prediction equations can also be derived from the first-order and second-order derivative of the absorption zero-order spectra. The first derivative eliminates the general intensity effect of the spectrum and simplifies the baseline selection and the second derivative removes the slope effect.

However, the use of derivative FTIR strongly affects the sensitivity of spectrometric measurement, and thus it must be avoided when constituents are present in the sample at very low concentration values.

Derivation also improves the identification of absorption bands. The selection of the wavelength is thus simplified and the prediction equations obtained give satisfactory results.[17] The quotients of first or second derivatives have also been tested in a simple regression for predicting quantitative values. The inconveniences of these derivation methods are the choice of the calculation steps and, for the quotients of the derivatives, the choice of the terms.

Multilinear regression applied to diffused reflected MIR has only been developed in a few cases. These examples show that it is possible to measure concentrations with satisfactory correlation coefficients.

The use of multilinear regression may lead to prediction equations that are unstable due to the nature of the spectral and quantitative data. The calibration of an instrument, step by step, by multilinear regression does not allow the control of the validation of the prediction equation. The interpretation of the selected wavelengths is not always easy and provides little information on the nature of the samples, owing to possible correlations between quantitative chemical data and spectral deformations.

Prediction equations that have been established from absorbance values do not completely take into account spectral deformations. This problem can be partly solved by using second derivatives.

Another inconvenience of step-by-step multilinear regression, applied to collections of continuous spectra, is that the number of data to be processed is considerable. McClure et al.[18] proposed that the corresponding Fourier coefficients should be calculated. In fact, it was shown that less than 100 coefficients are necessary to describe a spectrum. The selection of the variables of the prediction equation is then performed on these Fourier coefficients. The results of McClure are of similar precision to those obtained by traditional methods. The search for the regression terms is hereby simplified due to the diminution of the number of variables analyzed.

2.2.3 Least Squares Method

The adjustment of the curve following the least squares criterion is based on a linear model. A spectrum S can be expressed as a linear combination of spectra of its constituents, Equation (4):

$$S = S_{i=1}^{n} a_i c_j \qquad (4)$$

where j is the number of constituents, c_j the concentration of the jth constituent and a_i the coefficients obtained for each constituent.

The adjustment of the curves following the least squares criterion is performed as follows: the spectra of pure constituents are measured and the coefficients a_i of the linear combination are calculated by multiple linear regression. The constituents' concentrations are thereby calculated using the coefficients a_i instead of the absorbances as in the stepwise multilinear regression. The advantages and inconveniences of the method are summarized in Table 1.

2.2.4 Classical Least Squares Model

This method is based on the use of Beer's Law to extend the calculation of the absorption coefficients across a

Table 1 Advantages and disadvantages of least squares regression

Advantages	Disadvantages
Easy to understand and calculate	Requires isolated spectral bands that are solely related to the constituent(s) of interest
Calculations are very fast	Cannot be used for complex mixture samples in which the individual constituents have overlapping spectral bands
Used primarily for simple samples: pure compounds, binary mixtures, etc.	Band selection can be difficult or impossible if spectrum of property of interest is not known
	Selecting correct polynomial can be difficult; most spectroscopic systems can be solved with a simple straight line, but this is not 100% true
	Large prediction errors will result from constituents with bands in the same region of the spectrum as the calibration band(s)

Reproduced with permission from J.H. Duckworth, 'Spectroscopic Qualitative Analysis', in *Applied Spectroscopy: A Compact Reference for Practitioners*, eds. J.W. Workman, Jr, A. Springsteen, Academic Press, London, 1998. © 1998 by Galactic Industries Corporation.

much larger portion of the spectrum than the least squares regression model.

Beer's law is rewritten as Equation (5):

$$A_l = K_l C \tag{5}$$

where the absorption coefficient and path length are combined into a single constant K. Measuring the absorbance of a single sample of known concentration and using these values to solve for K can easily solve this equation. Predicting the concentration of an unknown sample is as simple as measuring the absorbance at the same wavelength and rearranging Equation (5):

$$C = \frac{A_l}{K_l}$$

Typically, the CLS calibration method is most useful when applied to samples that have minimal or no interconstituent interactions. The primary application for CLS has been in the analysis of gas-phase samples.

Table 2 below summarizes the advantages and disadvantages of this method.

2.2.5 Inverse Least Squares Model

If the concentrations of all the constituents in the mixtures are not known, there may be a significant error when solving for the absorption coefficients of the known constituents by the CLS approach. One solution to this problem is by rearranging Beer's law and expressing it as Equation (6):

Table 2 Advantages and disadvantages of CLS method

Advantages	Disadvantages
Based on Beer's law	Requires knowledge of the complete composition (concentration of every constituent) of the calibration mixtures
Calculations are relatively fast	Not useful for mixtures with constituents that interact
Can be used for moderately complex mixtures	Very susceptible to baseline; the response at a particular wavelength is due entirely to the calibration constituents
Calibrations do not necessarily require wavelength selection. As long as the number of wavelengths exceeds the number of constituents any number (up to the entire spectrum) can be used	
Using a large number of wavelengths tends to give an averaging effect to the solution, making it less susceptible to noise in the spectra	

Reproduced with permission from J.H. Duckworth, 'Spectroscopic Quantitative Analysis', in *Applied Spectroscopy: A Compact Reference for Practitioners*, eds. J.W. Workman, Jr, A. Springsteen, Academic Press, London, 1998. © 1998 by Galactic Industries Corporation.

$$C = \frac{A_l}{\varepsilon_l l} \tag{6}$$

or, by combining the absorption coefficient (ε_l) and the path length (l) into a single constant as with CLS, express it as Equation (7):

$$C = PA_l + E \tag{7}$$

where, as before, C is the constituent concentration, A_l is the absorbance at the wavelength l, and E is a matrix of concentration (not absorbance) errors.

Because it is not necessary to know the composition of the training mixture beyond the constituents of interest, the ILS method is better suited to more complex types of analysis not handled by the CLS approach. This method has been used for samples ranging from natural products (such as wheat, wood, cotton and gasoline) to manufactured products.

The major features of this method are summed up in Table 3 below.

2.3 Eigenvector Quantification Methods

2.3.1 Principal Component Regression

Multidimensional statistical analyses, such as principal component analyses (PCA), describe variation in multidimensional data by few synthetic variables. These synthetic

Table 3 Advantages and disadvantages of ILS

Advantages	Disadvantages
Based on Beer's law	Wavelength selection can be difficult and time-consuming; must avoid collinear wavelengths
Calculations are relatively fast	Number of wavelengths used in the model is limited by the number of calibration samples
Multivariate model allows calibration of very complex mixtures because only knowledge of constituents of interest is required	Generally, a large number of samples are required for accurate calibration
	Collecting calibration samples and measuring via a primary calibration can be difficult and tedious

Reproduced with permission from J.H. Duckworth, 'Spectroscopic Quantitative Analysis', in *Applied Spectroscopy: A Compact Reference for Practitioners*, eds. J.W. Workman, Jr, A. Springsteen, Academic Press, London, 1998. © 1998 by Galactic Industries Corporation.

variables are linear combinations of all the original variables and have the advantage of having no correlation with each other. Simpler descriptions of data sets are thus obtained with minimal loss of information. These treatments were used for morphological analysis of spectra[19] and for graphical representation of spectra similarity.[20]

PCA is applied to the full spectra that are centered prior (to PCA) according to Equation (8):

$$X_{ij} = A_{ij} - A_j - A_i + A \tag{8}$$

where X_{ij} = centered data; A_{ij} = spectral data ($\log 1/R$) of spectrum i and wavelength j; A_j = mean value of spectral data at wavelength j for every spectrum; A_i = mean value of spectral data of spectrum i for every wavelength; and A = average mean of all spectral data in the collection.

Principal component regression (PCR) was used to establish a prediction equation. PCR is basically a multilinear regression applied to scores and loadings assessed by PCA,[21,22] being the coordinates of data in the new orthogonal axis and the loadings of the directional vectors of the new axis related to the preceding ones. Interest in the introduction of scores according to their predictive ability has already been shown.[23,24]

Concentrations are predicted according to Equation (9):

$$\mathbf{C}_{nl} = \mathbf{X}_{\mathrm{nk}}\mathbf{V}_{\mathrm{kp}}\mathbf{R}_{\mathrm{p}l} \tag{9}$$

where **C** is the column vector of predicted concentrations, **X** is the centered matrix of spectral data, **V** is the matrix of latent vectors of PCA, and **R** is the column vector of the regression coefficients of the prediction equations. n, k, p are respectively the number of samples, the number of wavelengths and the number of significant principal components. The product $\mathbf{V} \cdot \mathbf{R}$ is a vector, the components of which may be interpreted in terms of absorption bands. Plotting the components against the corresponding wavelengths gives a spectral pattern. Peaks correspond to absorption bands which are characteristic of the measured chemical constituents. Troughs indicate that when the concentration increases, the corresponding absorption bands will decrease.[25]

The advantages and disadvantages of this method are indicated in Table 4.

2.3.2 Partial Least Squares

The partial least squares (PLS) method calculates from spectral and concentration or chemical data new variables termed ''factorial coordinates'' which are meaningful with regard to the chemical variables that have to be predicted.[26] The first coordinate is calculated so as to predict as much as possible the chemical variable and the spectral data. The nonpredicted part of the chemical variables and of the spectral data, that is the residuals, are calculated. The second coordinate is then determined so as to best predict the residuals of the chemical variables and of the spectral data. The new residuals are then calculated and the procedure is repeated until a

Table 4 Advantages and disadvantages of PCR analysis

Advantages	Disadvantages
Does not require wavelength selection; any number can be used, usually the whole spectrum or large regions	Calculations are slower than those of most classical methods
Larger number of wavelengths gives an averaging effect, making the model less susceptible to spectral noise	Optimization requires some knowledge of PCA; models are more complex to understand and interpret
PCA data compression allows use of inverse regression to calculate model coefficients; can calibrate only for constituents of interest	No guarantee that PCA vectors directly correspond to constituents of interest
Can be used for very complex mixtures because only knowledge of constituents of interest is required	Generally, a large number of samples are required for accurate calibration
Can sometimes be used to predict samples with constituents (contaminants) not present in the original calibration mixtures	Collecting calibration samples can be difficult; must avoid collinear constituent concentrations

Reproduced with permission from J.H. Duckworth, 'Spectroscopic Quantitative Analysis', in *Applied Spectroscopy: A Compact Reference for Practitioners*, eds. J.W. Workman, Jr, A. Springsteen, Academic Press, London, 1998. © 1998 by Galactic Industries Corporation.

satisfactory precision for the estimation of the chemical variable is obtained.

The new spectrum S is rewritten as Equation (10):

$$S = S + Sa_i c_i + r \tag{10}$$

where S is the mean spectrum of the collection, a_i the ith factorial coordinate, c_i the ith factor and r the residual.

The factors are estimated while calculating the chemical data coordinates and can be written as Equation (11):

$$p = p + Sa_i d_i + rp \tag{11}$$

where p is the mean value of the chemical data, a_i is the ith factorial coordinate calculated by the equation, d_i is the ith factor associated with the chemical data, and rp is the residual.

The d_i factors are estimated during the calculation of the coordinates similarly to the c_i factors defined above. The chemical values for an unknown sample are estimated by calculating a_i, the factorial coordinates, with Equation (10) and then by applying Equation (11) so as to determine the values of p.

There are actually two versions of the PLS algorithm: PLS-1 and PLS-2. The differences between these two methods are subtle but have very important effects on the results. Like the PCR method, PLS-2 calibrates for all constituents simultaneously: one set of scores and one set of eigenvectors or loadings are obtained for calibration during the spectral decomposition. Therefore, the calculated vectors are not optimized for each individual constituent. In PLS-1, a separate set of scores and loading vectors is calculated for each constituent of interest. The method should give more accurate predictions than PCR or PLS-2.

Table 5 summarizes the advantages and disadvantages of the PLS methods.

Table 5 Advantages and disadvantages of PLS method

Advantages	Disadvantages
Combines the full spectral coverage of CLS with partial composition regression of ILS	Calculations are slower than most classical methods, especially PLS-1. Models are more abstract, thus more difficult to understand and interpret
Single-step decomposition and regression; eigenvectors are directly related to constituents of interest rather than largest common spectral variations	Generally, a large number of samples are required for accurate calibration
Calibrations are generally more robust provided that calibration set accurately reflects range of variability expected in unknown samples	Collecting calibration samples can be difficult; must avoid collinear constituent concentrations
Can be used for very complex mixtures because only knowledge of constituents of interest is required	
Can sometimes be used to predict samples with constituents (contaminants) not present in the original calibration mixtures	

Reproduced with permission from J.H. Duckworth, 'Spectroscopic Quantitative Analysis', in *Applied Spectroscopy: A Compact Reference for Practitioners*, eds. J.W. Workman, Jr, A. Springsteen, Academic Press, London, 1998. © 1998 by Galactic Industries Corporation.

2.3.3 *Comparison of Partial Least Squares and Principal Component Regression Methods*

It should be noticed that a spectrum obtained by least squares curve adjustments is in fact a product of spectra similar to the additive model in PCA. The resulting spectra are similar to eigenvectors and the variables with which they are associated are calculated. However the variables and the spectra are not orthogonal. The major advantages of PCA over least squares methods are the orthogonality of the factorial coordinates, but, most importantly, it calculates typical spectra and hence extracts the major characteristic wavelengths.

In the method of Hruscka and Norris,[27] the calculation basis from the typical spectra must be chosen. Even if they are carefully selected so as to be as different as possible, they are nevertheless less dissimilar than eigenvectors are and thus do not detect the most characteristic frequencies of constituents. As a matter of fact, PCA is a more informative method than least squares curve adjustment methods.

The PLS method is interestingly similar to PCA, since factors and coordinates are calculated. The difference lies in the mode of calculation. Data are estimated as a function of the characteristic parameters to be measured. As a consequence, the first calculated coordinates are more predictive. With regard to this, PLS is more powerful than PCA since the information on the first axes is more predictive. However, Martens and Jensen[26] showed that the total number of axes introduced into the regression is identical and that the precision is similar. The two methods are almost identical with regard to the results obtained. The major advantage of PCA is that the underlying theory is simpler than PLS. Hence modeled spectra are easier to interpret.

3 MEASURED PARAMETERS

In an industrial process it is often necessary to monitor and control the successive steps. As is mostly the case in

chemical processes, the methods used for these controls are rather long. It becomes more advantageous to develop alternative methods such as spectroscopic methods, which are more rapid than classical ones, to measure both physical and chemical parameters.

Spectroscopic methods are very interesting when real-time-based measurements are necessary. IR can provide information on raw materials and on the corresponding final products, but additionally it provides an excellent way for process control.

These measurements are advantageous only when it is possible thereafter to control the measured parameter with the aim of improving the efficiency of the process. These parameters are generally physical or chemical.

3.1 Chemical Parameters

It is evident that foods and pharmaceutical products should be carefully analyzed for security reasons and, for these products, the concentration of sample components is extremely important for health and toxicological reasons.

Several parameters can be measured: (i) IR analysis can in many cases be used to analyze the degree of contamination of a sample, hence its purity. In the food industry these aspects are not only important but are moreover imposed by regulations and by the existing quality standards requirements which are very constraining in several countries; (ii) chemical characteristics, the identification of functional groups (OH, NH_2, COOH, etc.) or identification of constituents (sugars, alcohols, fatty acids, proteins, etc.).

The type of calibration is defined as a function of the products to be analyzed. IR spectrophotometers will need to have the species ''introduced'' in all possible matrixes that might occur in a particular reaction/process. It is however possible to select a wavelength and to use the Beer–Lambert law. When several absorption bands recover, it is still possible to select a specific wavelength by using powerful multidimensional data analysis.

In complex mixtures, powerful mathematical tools, such as PLS or PCR, are used for the quantification of a particular constituent. These mathematical treatments can be applied to a part of the spectrum or to the whole spectrum.

It should not be forgotten that the accuracy of the prediction is dependent on the accuracy of the reference method. It should also be remembered that spectroscopic calibration methods demand as much time and resources as a chemical method would demand in order to guarantee their traceability. The advantages of using such methods are their relatively low costs, their accuracy and their speed.

3.2 Physical Parameters

In addition to the concentration values of sample constituents, physicochemical parameters in fluids can be monitored by IR or NIR. These vibrational spectroscopic techniques are very sensitive to matrix effects such as those existing in the presence of hydrogen bonds. Among the physical parameters most currently measured are:

- Viscosity, which is influenced by the number of hydrogen bonds in the samples. It is therefore possible to measure viscosity by IR spectroscopy.
- Density, since it directly influences the transmission of incident light.
- Color, which can be obtained by an ultraviolet/visible (UV/VIS) spectrophotometer; the advantage of FTIR lies in the possibility of verifying that the color is really given by the supposed constituents of the samples.
- Distillation temperature, or practical parameters such as the octane number in gasoline, are closely related to the sample composition and can be easily derived from the IR spectra using appropriate mathematical models.

4 APPLICATIONS OF DIRECT QUANTITATIVE INFRARED SPECTROSCOPY

4.1 Infrared Spectroscopy in Food Analysis

To date, the ease of utilization of spectroscopic methods such as NIR, MIR, UV/VIS and also Raman or nuclear magnetic resonance (NMR) is such that they can be used in routine analysis in quality management and control of food industry production.

NIR is the most commonly used spectroscopic method in the food industry for the quantification of major biochemical constituents. Its success is primarily due to its simplicity and its rapidity. Analytical results can be obtained in few seconds, even if the samples are opaque to IR radiation, such as solid substrates.

The first trials were performed in 1960 under the direction of the United States Department of Agriculture (USDA). A series of investigations were undertaken in order to develop physicochemical methods for rapid characterization of foodstuffs. Norris[28] et al. rapidly assessed the advantage of using the NIR range: NIR is the only region suitable for the diffused reflection technique, which does not require dilution of samples in an optically inactive substance like potassium bromide. In 1962, he developed the first apparatus for the quantification of water by NIR spectroscopy.[28] These trials showed that

constituents such as proteins, lipids and starch hindered the measurement of water content. This problem was alleviated with the application of multilinear regression to spectral data. This not only improved the precision of the quantification of water but also allowed the quantification of other constituents.

From 1970, numerous types of apparatus were specifically devised for specific analytical applications and were commercialized. These devices were spectrophotometers with interferential optical filters and were coupled to microcomputers. The filter-based NIR instruments were able to perform few measurements at some specific wavelengths only. Nowadays, the most sophisticated spectrophotometers are built with interferometers and make use of Fourier transform signal processing.

The field of application of NIR spectroscopy is very wide: it covers the quantification of major constituents such as water, proteins, lipids and sugars in almost every foodstuff.[2,3]

The incorporation of the Fourier transform technique into MIR spectrometers[29] and the advent of new and easy to use techniques[30] such as ATR, photoacoustic spectrometry (PAS), diffused reflectance infrared Fourier transform (DRIFT) has largely contributed to the progress of IR-based analytical methods. In 1991, several workers showed that ATR was potentially a powerful tool for the study of food products.[31–33] With the application of Fourier transforms, it was possible to obtain MIR spectra by diffused reflection. Fuller and Griffiths[34] and Depecker et al.[31] demonstrated the advantages of the diffused reflection technique for the study of biological samples.

The use of MIR spectroscopy for the analysis of foodstuffs is still restricted. Few example applications have been described; Renard et al.[35] used MIR for the analysis of cereals and related products. Other applications for the analysis of milk and dairy products have been proposed.[36]

We will now describe the use of spectroscopy for direct spectroscopic quantitative analysis in the study of lipids, carbohydrates and proteins. We will then show the possible applications of IR spectroscopy to the study of enzymatic reactions. Finally, examples of quantification through FTIR spectrometry coupled to other analytical techniques such as FA, vapor generation, gas chromatography (GC), microwave-assisted vapor-generation, and sequential injection analysis (SIA) will be reviewed (Figures 2–4).

4.1.1 Lipids

The rapid control of the quality of lipids is a major preoccupation in the food industry. NIR has long been used for this purpose. Recent developments in MIR

Figure 2 Manifold employed for vapor generation FTIR spectrometry. Inset (a) glass-bead packed reactor, and (b) open reactor.

Figure 3 Manifolds employed for vapor generation FTIR analysis. (a) Single-channel flow manifold with a nitrogen carrier flow. (b) Closed FIA manifold.

spectroscopy, such as the advent of the ATR method, which has solved the water absorption problem, have made its use in food analysis easier.

4.1.1.1 Measurement of the Unsaturation Degree of Lipids Holman and Edmondson[37] have shown that the increase or decrease in the intensities of bands in the 2190–2150 nm region is related to the unsaturation degree of lipids. They attributed the bands at 1180, 1680, 2150 and 2190 nm to the group =C−H "*cis*". The bands at 1680 and 1180 nm are the first and second harmonics respectively. They also noticed that NIR did not allow the identification of =C−H "*trans*" in lipids. In 1959, Holman estimated the unsaturation degree of lipids by NIR, MIR and by the iodine index method. Results obtained by MIR and by the classical chemical method were similar. However, since *trans*-unsaturation could not be detected by NIR, the unsaturation degree was systematically underestimated with NIR. Fenton and Crisler[38] developed a NIR-based analytical method in order to determine the *cis*-unsaturation degree in free fatty acids from refined oils. Murray[39] also showed that the absorption bands at 2150 nm and 2190 nm indicated the existence of a *cis*-double bond in free fatty acids.

Wheeler[40] has intensively investigated the structural analysis of lipids through their MIR absorption spectra. MIR is now used routinely for the determination of *cis*- and *trans*-fatty acids in oils and fats and has been adopted as an official routine method by the American Oil Society (AOCS) and the International Union of Pure and Applied Chemistry (IUPAC).

Ahlers et al.[41] have studied the unsaturation degree of pure and sterified free fatty acids. Their investigation was based on the measurement of the intensities of absorption bands at 3015 and 967 cm^{-1}, which were attributed to elongation of *cis* =C−H groups and −CH=CH− *trans*-deformation respectively. The intensity of these two bands increases with the unsaturation degree. The band at 3010 cm^{-1} also often determined the unsaturation

Figure 4 Manifold employed for microwave-assisted vapor-generation FTIR spectrometry: $I_1 = 88$ cm, $I_2 = 100$ cm, $I_3 = 60$ cm.

degree and was attributed to valence vibration of the =CH *cis*-group. Kochhar and Matsui[42] have performed the determination of free *trans*-fatty acid content by a transmission method; the band characteristic of C−H in a *trans* double bond is located at 965 cm^{-1}.

O'Connor[43] has conducted detailed studies in order to differentiate between the *cis*- and *trans*-isomers that were associated with unsaturation.

Arnold and Hartung[44] have determined the unsaturation degree of 25 different oils in the 3700–3200 cm^{-1} region. The unsaturation degree is proportional to the quotient of the intensity of bands at 3015 cm^{-1} and 2860 cm^{-1}. These bands are attributed to the symmetric valence vibration of the $-CH_2-$ group.

Anderson et al.[45] have developed a spectroscopic method for the precise determination of the unsaturation degree in butters and oils. They validated the results found from their method by comparing them with those obtained by the iodine index method. The correlation between IR absorbance and iodine index was verified for butter and mono-hydrogenated oils. Significant correlation coefficients ($r = 0.97$) were obtained (Ahmed and Helal[46]) between absorbance at 1015 cm^{-1} (due to olefin *cis*–*trans* isomerism during hydrogenation) and the iodine index method.

With the use of ATR, Belton et al.[47] have quantified *trans*-unsaturated fatty acids in oils and lipids. The characteristic *trans* =C−H band determined by Belton was located at 976 cm^{-1}.

4.1.1.2 Lipids Determination NIR has long been used as a standard routine method for quantification of lipids in foods and in particular in milk and related compounds.[48–50]

Sato and Kawano[51] showed that characteristic bands of lipids in milk are featured at 1164, 1660, 2144 and 2176 nm. These bands are attributed to *cis*-unsaturations in the fatty acids existing in milk.

Lipids have been quantified by NIR in a great variety of substrates: meat products,[52,53] cereals[54] and oleaginous seeds.[55–57]

In 1986, Murray[39] showed, from a collection of NIR spectra of free fatty acids, that the only difference that can be noticed was in the absorption bands related to the number of CH_2 groups.

MIR absorption bands have been used for the quantification of lipids in milk.[58,59]

With the use of devices equipped with interferential filters, the quantification of lipids by measuring the absorption at 1754 cm^{-1} (characteristic of ester groups) is possible. Since there are on average three ester links in most molecules, this technique is in fact a mean for counting molecules. If the mean molecular weight is constant, the absorption measurements at 1754 cm^{-1} allow the precise assessment of the amount of fats. However, milks show great variations in their fatty acid composition according to their origin and the period of sample collection. In order to overcome this problem, a second filter can be used. This filter permits measurements between 2940 and 2860 cm^{-1} and allows the determination of the average size of fatty acid molecules by measuring the number of C−H bonds.

4.1.2 Quantitative Analysis of Carbohydrates

Both NIR and MIR have been employed for carbohydrate determination in foods.

4.1.2.1 Near Infrared Spectroscopy of Carbohydrates Numerous workers have used NIR for the analysis of sugar contents in foodstuffs. McClure et al.[60] have directly measured total reducing sugars in tobacco leaves. Giangiacomo et al.[61] predicted, with very good precision, the fructose, glucose and sucrose contents of apple juices or of reconstituted[62] mixtures of carbohydrates. Lanza and Li[63] were able to predict total sugar content in fruit juices; Osborne et al.[64] measured sugars in biscuits; Kaffka and Jesenszky[65] determined sugars in wines; Baker and Norris[66] determined the sugar content in cereals and other foodstuffs;[67] Robert et al.[68] analyzed apples, and Ootaka[69] studied tomatoes. Rambla et al.[70] determined glucose, fructose, sucrose and total sugar contents in fruit juices by means of the PLS data treatment of NIR measurements.

Baker[67] quantified starch content and total soluble sugars in fast foods. Bertrand et al.[25] measured total parietal constituents contents in wheat products, including various types of semolina.

NIR can be used to determine the state of starch degradation but this characterization is not supported by a molecular approach. Osborne and Douglas[71] have applied NIR spectroscopy to the prediction of this parameter. In their investigations, they used commercial flour with different degrees of starch degradation. The procedure is useful for the classification of flour according to the extent of starch degradation.

The potential application of NIR spectroscopy in the sugar industry has been assessed. These studies were undertaken on sugarcane juices[72,73] and on beetroot juices.[74,75] Studies performed using an InfraAlyser 450 equipped with 20 filters have shown that it is possible to predict with good precision the sucrose content, as well as the Brix index and humidity, from diluted raw juices. However, these studies were performed on a limited number of samples. In 1989, Ames et al.[76] collected and analyzed up to about 600 NIR spectra of raw sugarcane juices that were collected from several centers in Australia in 1987. The InfraAlyser 500 allowed investigation in the

whole range covering 1100–2500 nm. The results obtained appear to be satisfactory according to the standards of routine analysis in industrial processes. However, a systematic deviation between the polarimetric values and sugar contents predicted by NIR spectroscopy during particular periods in the sugarcane collection has been noticed.

Altenburg and Chou[77] proposed working at 882.6 nm in NIR to determine sugar contents in raw sugarcane juices with a NIR-polarimeter. This work on IR spectroscopy were encouraged by the International Commission for the Uniform Methods of Sugar Analysis (ICUMSA).[78]

4.1.2.2 Mid-infrared Spectroscopy of Carbohydrates

MIR spectroscopy has been used since 1950 for the study of carbohydrates. Structural analysis of carbohydrates from their MIR spectra has been thoroughly investigated.[79–82] Apart from starch, the sugars that are of most interest to the food industry are sucrose, glucose and fructose.

Barker et al.[80] have systematically studied aqueous solutions of carbohydrates by MIR in an attempt to identify bands that are characteristic of sugars in aqueous solutions.

In nonaqueous solvents, there exist IR spectroscopy studies that were carried out on model molecules that featured patterns characteristic of carbohydrates.[82] These investigations essentially focused on the O–H absorption band in the 3700–3300 cm^{-1} region, with the aim of determining sucrose chelation in nonaqueous solutions.

Only a few works are concerned with MIR spectroscopy for direct sugar quantitative determinations. Dupuy et al.[83] have quantified sugars in fruit juices and syrups but they suggested that the results obtained with diffused reflectance did not meet the standards required for a possible use in quality control, particularly for quantitative analysis.[84]

Cadet et al.[33] were the only team to investigate the use of MIR spectroscopy for the study of sugarcane juices. Their work was motivated by the fact that the price of sugarcane is estimated by its sucrose content. Not only is the method used to determine sucrose content in sugarcane fundamental, but also the delay and costs of the analyses are important. Polarimetry and high-performance liquid chromatography (HPLC) are the most commonly used techniques to measure sucrose content in sugarcane. However, it has been shown that polarimetric measurements underestimate sugar content. Measurements by HPLC are not precise enough and the results are not easily reproducible for routine analysis and need a preliminary sample clarification before the analysis is carried out.

MIR ATR can be used to study samples that are difficult to analyze. This is the case for raw sugarcane juice, which is completely opaque.

PCA and PCR were subsequently used to assess and describe MIR spectral data of crude sugarcane juices. The method was validated on a panel of 1267 samples representative of a sugarcane collection.

A peak at 997 cm^{-1} was the most important for the quantification of sucrose. After PCR, the first introduced component gave a correlation coefficient value towards sucrose equal to 0.878 and, with the second introduced component, this value reached 0.949. The bias and the standard deviation of the differences between the reference value and the predicted value are 0.041 g/100 mL and 0.289 g/100 mL respectively. When compared to values obtained between the reference value and direct polarimetric values (−0.163 and 0.087 g mL^{-1}) these values show that the proposed method yields values that are very close to real ones. This method, which uses MIR ATR, allows direct measurements of sucrose content in raw juices and hence is more advantageous for routine analysis and industrial processes than the polarimetric method. Furthermore, the proposed method eliminates costs linked to consumption of the polluting agent lead acetate, and eliminates the lengthy filtration phase. The whole procedure, from raw sugar analysis to prediction of sucrose content, needs only about 25 s for each sample.

Vonach et al.[85] used MIR transmission spectrometry for the direct determination of glucose in human blood.

4.1.3 Quantitative Analysis of Proteins

Proteins are macromolecular structures constituted of polypeptide chains of amino acids that are linked by peptide bonds. It is common to distinguish the different structure and organization of proteins following the nature and the repetitive character of the interactions that exist within the macromolecules.

The primary structure of a protein is defined as its sequence of amino acids.

The secondary structure of a protein is defined by the spatial arrangement of the amino acids in the polypeptide chain. A limited number of particularly favorable spatial configurations are adopted by atoms of each amino acid in a polypeptide chain, which folds to give rise to the well-known secondary structures: the alpha helix and beta strands, as well as less regularly defined structures like turns, loops and coils.

The tertiary structure of a protein is the spatial arrangement of the whole polypeptide chain and arises from the packing of different folding regions owing to interactions between the side chains of the constituent amino acids.

The quaternary structure of proteins describes the arrangement of several polypeptide chains that are associated to form a supramolecular structure.

MIR spectroscopy has been widely used for the determination of polypeptides and protein secondary structures.[86] Miyazawa and Blout[87] carried out normal coordinate calculations on model compounds, which showed three strong IR bands of proteins, called amide I, II and III. The most representative spectral region is that between 1600 and 1700 cm^{-1}, which is characteristic of amide I.

4.1.3.1 Predicting Protein Secondary Structures The secondary structure of a protein is difficult to investigate by physical analytical methods. MIR spectroscopy provides a gateway for studying secondary structures, in particular for quantifying the relative proportioning of alpha helix, beta sheets, turns, etc.

The position of the amide I and II absorption bands depends on the dihedral angles in the peptide units, and hence on the type of periodical structures existing in the investigated protein molecule.[88] Several methods for predicting secondary structures in proteins from IR spectra have been subsequently developed.

Two major methods have been described:

- Methods based on direct analysis of spectra, either by deconvolution,[89] or by calculation of the second derivative.[90]
- Methods that use calibration from a collection of spectra of proteins of known structures.[91,92]

In 1990, Dousseau and Pézolet[93] showed that vibrational spectroscopy in the MIR region can be used to determine with a good precision the secondary structure of proteins. The results obtained can be favorably compared to those obtained by circular dichroism or by Raman spectroscopy.

The proposed method consists of the following steps: subtraction of the spectrum of water, baseline correction and normalization of the spectra, and application of PLS to the corrected spectra – for the prediction of secondary structures.

FTIR spectroscopic studies on membrane proteins were at first mainly of a qualitative nature. Recent developments provide quantitative information as well. For example, PLS FTIR predictions of the secondary structure of the following membrane proteins have been performed: Ca-ATPase, cytochrome oxidase, glucose transporter, rhodopsin, porin, etc. Methods used for quantitative analysis are either based on curve-fitting techniques or pattern recognition.[94]

4.1.3.2 Quantitative Analysis of Proteins The quantitative analysis of proteins by NIR spectroscopy is an alternative to the classical Kjeldahl chemical method and is, as a matter of fact, of great economic importance.

The quantification of proteins in cereals is by far the most important application of NIR spectroscopy. Proteins present several characteristic absorption bands in NIR. The most intense band is located in the 2170 and 2180 nm region.[95] This band is attributed to a combination of the amide I band with that of the amide III band.[96] Quantification of proteins by NIR is as precise as quantification with the Kjeldahl method.

In MIR, a method for the quantitative measurement of α-amino groups from amino acids, peptides and proteins has been proposed by Cadet.[97] The spectral region where the characteristic absorption bands of such groups are located ranges between 1200 cm^{-1} and 1900 cm^{-1}. Water shows a major absorption band in this region (1500–1700 cm^{-1}). This superimposes on the amide I and II bands.

The standard deviation for each and every wavelength, calculated for all the spectra of the calibration set, shows the existence of two absorption bands in the 1500–1900 cm^{-1} region. This means that the observed variations in this zone are not only due to water but are also due to two peaks centered at 1650 cm^{-1} and 1540 cm^{-1} (with a trough at 1600 cm^{-1}) that are characteristic of proteins.

Good predictions were obtained; the mean and standard deviation associated with the predicted concentrations of α-NH_2 (protein) content were 0 g mL^{-1} and 0.12 g mL^{-1} respectively. Hence, it has been clearly established that it is possible to determinine the α-NH_2 content of foods from their MIR spectra.

4.2 The Use of Infrared Spectroscopy in Enzymatic Analysis

Enzymatic studies are often carried out in two different ways: (i) by the determination of the amount of a product or a reagent after reaction through a generally lengthy chemical method or, (ii) by using coupled enzymatic assays, so that a chromophore, like NAD(P), was oxidized or reduced and was finally titrated. This second method is more often used for quantitative analysis through enzymatic reactions that generally do not give chromophoric or fluorescent products directly. However, the use of other enzymes in coupled assays implies a good understanding of their kinetics and can make some studies difficult. As for example is the variation of the activity of an enzyme according to pH. So, for the assay of enzymes with products and reagents that have no absorption in the UV/VIS region, it may be interesting to avoid coupled enzymatic assays and to proceed in a single step.

Recent developments in analytical IR spectroscopy, and particularly the possibility of connecting computers

to spectrophotometers, make this technique easier and give it new scope. Cadet et al.[98] first investigated the potential of MIR spectroscopy combined with multidimensional statistical analysis, using an ATR cell to allow a one-step enzymatic assay. In this way, they proposed an alternate method for enzyme study. Hydrolytic activity of β-fructosidase, with sucrose as substrate, was monitored. Familiar progress curves can be obtained by quantification of the remaining substrate, and enzymatic studies of the kinetic properties of the enzyme become possible. The proposed method offers an alternate analytical procedure for enzyme studies. It also allows the identification of structural changes in a compound during a reaction. Furthermore, the study of the enzyme can be carried out directly without resorting to coupled assays. The authors suggested that the method could be extended to any enzyme, with appropriate calibration.

Schindler et al.[99] proposed an automated method for the determination of amyloglucosidase (glucan 1,4-α-glucosidase) activity in aqueous solutions. Amyloglucosidase is produced from *Aspergillus niger* by submerged fermentation and is frequently used in industry, e.g. for starch liquefaction in food and pharmaceutical industries.[100] The method is based on the direct FTIR spectrometric monitoring of starch hydrolysis catalyzed by amyloglucosidase. It is shown that spectral changes caused by the enzyme activity can be followed by the study of the MIR spectra, hence eliminating the need for additional consecutive reaction steps which are normally required to derive a reaction product detectable by conventional techniques such as UV/VIS spectroscopy or electrochemistry. Unspecific background absorption was eliminated by calculation of a difference spectrum between nonreacted starch and the reaction mixture. To guarantee optimum handling of the viscous starch solution and to obtain high sensitivity, a flow injection analysis (FIA) system using the merging zone approach and the stopped-flow technique was developed. Using a stopped-flow time of 5 min and a 55 g L^{-1} starch substrate solution, linear calibration curves from 50 to 2000 U^{-1} (830–33 300 nkat L^{-1}) were obtained. The coupling of a FTIR spectrometer with a flow system capable of performing chemical reactions in an automated, repeatable and reproducible way was proved to enhance the detection power of the FTIR instrument. By using this approach, a parameter, which is not accessible by a single FTIR measurement, could be successfully determined. Furthermore, this coupling has demonstrated new possibilities for the application of MIR FTIR spectrometry for remote process monitoring and process control and has been applied for the study of other enzymes.[75,101]

5 APPLICATIONS OF FOURIER TRANSFORM INFRARED ANALYSIS COUPLED WITH OTHER ANALYTICAL METHODS

FTIR spectroscopy has been traditionally used to obtain qualitative information of organic sample. But recently it has been demonstrated that FTIR spectroscopy is also an excellent tool to obtain accurate quantitative results from spectra obtained in solid, liquid or gaseous states, in spite of the general problems encountered when using traditional systems of IR measurements.[102–104]

Table 6 provides a picture of the main drawbacks of traditional systems of IR spectra acquisition and the different strategies that can be adapted to solve all these problems.

Among the problems which remain for general applicability of FTIR spectroscopy for quantitative analysis are the solvent and window material transparencies.[105] These are still the main reasons for a limited development in this field. For the analysis of aqueous samples by FTIR, it is necessary to use adequate transmittance or reflectance cells with water-resistant windows. The use of transmittance measurements requires very small path lengths, of the order of 25 µm, due to the strong water absorption, and the use of ATR cells involves poor sensitivity.

The vapor or gaseous state is very useful for carrying out determinations by FTIR. This is due to the high transparency of gases, the low background obtained for this kind of systems and the possibility of using multiple pass gas cells which can provide good sensitivity.[106,107] For these reasons, FTIR spectrometry has been extensively used for detection in GC[108–110] and also in combination with sample pyrolysis.[111–113] More recently, a new strategy for FTIR analysis based on vapor generation from small injected volumes of liquid samples has been

Table 6 Strategies for solving problems of IR spectra acquisition

Sample preparation	Problems	Solutions
Thin films Alkali halide disks	Difficulties in establishing the sample bandpass Bad repeatability	The use of internal standard The use of bands quotient
Gas cells	Leaks Problems in sample preparation Difficult standarization	Derivatization and pyrolysis IR Vapor phase generation
Liquid cells	Compatibility of the cell windows and solvents Difficulties in mounting and cleaning the cells	Use of adivent mixtures Vapor phase generation FIA/FTIR

developed.[6] This technique was applied to the quality control of solvent additives,[110] paint analysis,[7] gasoline component,[114] and to the determination of alcohol in aqueous samples like alcoholic beverages[115] and in blood.[116]

Many examples of on-line determination exist. Most of them deal with the chemistry of synthesis and with the food and pharmaceutical fields.

In recent years, FIA methodology has been incorporated into most branches of analytical chemistry. The second edition of Ruzicka and Hansen's book[117] included 588 references for the use of FIA in UV/VIS determinations, 123 in atomic absorption spectroscopy, 72 in spectrofluorimetry and only 4 in FIA/IR. These values grew up during the past decade. Below, some examples of applications are given.

FTIR has a better selectivity than UV/VIS spectrometry and provides an excellent tool for the determination of mixtures of compounds. On the other hand, in the last few years, FIA/FTIR has been demonstrated to be a synergistic combination highly appropriate for the quality control of drugs.[4,103,118–123]

In general, the analytical procedures developed for IR determination require the use of organic solvents, and frequently chlorinated solvents, such as CCl_4, $CHCl_3$ and CH_2Cl_2, are those that provide the best transparency in the IR range and the lowest limits of detection. However, these reagents are highly toxic and efforts must be made to replace these reagents or to reduce drastically the amount of solvents employed through the automation of measurements and the development of on-line recycling techniques. The FIA/FTIR methodology offers a fast and simple way for automating the sample and measurement operations and provides a clean analytical method.[13,124]

FIA offers an inexpensive and versatile means for the automation of analytical procedures, and hence it has been incorporated in many different techniques.[117,125–127] FTIR spectroscopy is a powerful technique for qualitative and quantitative organic analysis[128,129] and this has led to the development of a flow injection procedure for use with FTIR analysis.

The use of flow injection in conjunction with IR analysis provides a simple and reproducible way to fill and clean the liquid cells. It also allows (i) the rapid automation of the determination and (ii) a strong reduction in the consumption of reagents and in the production of wastes.[130] The use of FTIR permits[121,131–134] an increase in the sensitivity, by accumulating a series of scans in the stopped-flow mode, the continuous monitoring of the baseline of the spectra and the accurate determination of the maximum of absorbance bands.

The recent development of FA procedures in the field of IR spectrometry has solved some of the many drawbacks of quantitative determination using this technique:[121,130–132,135] (i) repeatability and accuracy of the determinations have been improved;[5] (ii) the possibility of direct analysis of real samples has been enhanced;[136] (iii) easy and fast methods for the quantitative quality control of several compounds in the same sample have been provided[137] and (iv) the sensitivity of FTIR determination has been increased by means of on-line coupling with concentration techniques.[138]

The use of FA FTIR derivative spectrometry permits additionally the direct determination of compounds in real samples, without requiring previous separation or clean-up procedures and without problems in establishing the baseline[114] (Figures 5–7).

5.1 Fourier Transform Infrared Determination in Pharmaceuticals

IR spectrometry provides a useful way to identify drugs.[118,137–140] However, traditional techniques employed to obtain the IR spectra, such as alkali halide disks, mulls and thin films, are not adequate either for quantitative analysis, or for the use of transmittance spectra. For this reason, UV spectroscopy was for a long time, and is still currently, employed in the analysis of pharmaceuticals rather than IR. The use of flow cells for handling appropriate solvents and with well-selected spacers and windows opens the possibility of carrying out quantitative IR determinations of drugs, especially for the development of automated procedures based on FIA. Ibuprofen is a nonsteroidal anti-inflammatory analgesic that can be quantified by the combination of FIA/FTIR[136] (Figure 8).

FIA has been successfully used for the determination of acetylsalicylic acid, caffeine,[133] dimenhydrinates and paracetamol.[103]

Propyphenazone and caffeine are important analgesic and stimulant drugs respectively, which are commonly used and combined in pharmaceutical formulations. A procedure has been proposed for the simultaneous FTIR determination of propyphenazone and caffeine in commercial pharmaceutical formulations.[13] The method involves the dissolution of the active principles in $CHCl_3$, followed by filtration of the sample solution, to remove the other molecules than "active principles". Propyphenazone is determined by absorbance measurements at 1595 cm^{-1}, using a baseline established between 2000 and 890 cm^{-1}, and caffeine by using the first derivative values at 1712 cm^{-1}, using propyphenazone and caffeine standards for external calibration. The method was applied in both stopped-flow and flow injection modes, providing precise and accurate results for the quantitative analysis of samples (Figure 9).

Figure 5 Manifolds employed for: (a) stopped-flow FTIR measurement, and (b) reversed FA.

Figure 6 Manifold employed for on-line solid phase extraction and on-line elution of caffeine.

Bouhsain et al.[120] proposed the simultaneous determination of paracetamol, acetylsalicylic acid and caffeine. The simultaneous determination of these three active principles can be performed by using multivariate calibration. Various numerical methods were proposed in combination with molecular spectroscopy, such as Kalman filtering and UV data,[141] multiple linear regression of the NIR reflectance data[142] and multivariate programs applied to UV measurement such as multicomponent simplex analysis and multic,[143] iterative

Figure 7 Manifold employed for vapor generation FTIR determination of carbonate in waters. Volumes and flow values are those corresponding to the best conditions of analysis. The porous silicone rubber tube has a 0.8 mm internal diameter, a 1.6 mm external diameter and a length of 60 cm.

target transformation factor,[143,144] step regression[145] and PLS regression.[120] The latter also developed a PLS/FTIR procedure for the fast and accurate simultaneous determination of paracetamol, acetylsalicylic acid and caffeine in commercial pharmaceutical formulations. This reduced preliminary sample treatment to the leaching of compounds to be determined from the pharmaceutical formulations with a 10% v/v solution of ethanol in dichloromethane in an ultrasonic water bath for 20 min, and providing the direct FTIR determination by using a simple matrix calibration including only eight standards.

Figure 8 Manifold employed for the FIA/FTIR determination of ketoprofen and on-line solvent recycling. $L_1 = 55$ cm, $L_2 = 78$ cm and $L_3 = 43$ cm.

Garrigues et al.[146] have developed a method for the determination of ibuprofen in pharmaceuticals by FTIR, using the carbonyl band, which the compound presents at 1710 cm^{-1} in carbon tetrachloride solution.

5.2 Fourier Transform Infrared Determination in Petroleum Products

The determination of aromatic hydrocarbons in naphthas and motor gasoline is necessary in several areas of the petroleum, petrochemical and related industries.[147] Detailed information on the aromatic composition of fuel materials, intermediates and commercial products is required for process development and quality control programmes. Legislation in several countries limits the upper concentration of some hydrocarbons in commercial gasoline.

Figure 9 Manifold employed for the clean simultaneous FTIR determination of propyphenazone and caffeine.

FTIR spectrometric techniques are known to provide a rapid means for the direct determination of aromatic compounds.[148] Gallignani et al.[4] proposed a FTIR procedure for the automated determination of benzene in gasoline, based on the use of FIA. The method permits the direct determination of benzene without any pretreatment of samples, with a limit of detection of 0.002% (v/v). Results found by direct analysis agree well with those obtained by off-line and on-line standard addition methods. A rapid quality control procedure was developed, based on the on-line injection of 1 : 10 diluted gasoline samples into a carrier stream of a 0.5% (v/v) solution of benzene in hexane; the baseline corresponds to the upper limit tolerated by the European Economic Community's law for gasoline. On the other hand, the American Society for Testing and Materials (ASTM) has proposed the IR batch determination of benzene in motor and aviation gasoline.[149]

Methyl *tert*-butyl ether is an antiknock agent commonly employed in unleaded gasoline.[114] The additive is frequently determined by GC in gasoline, in synthetics products and in estuarine waters and sediments. A NIR method has been applied to the direct measurement of methyl *tert*-butyl ether in gasoline with an associated standard error of 0.1% (v/v) by using the second overtone NIR region.[150]

Daton et al.[151] used a batch method for the determination of this compound in gasoline based on direct absorbance measurement at 851 cm^{-1} by using ATR. They obtained a relative standard deviation that ranged between 1 and 1.6% for the analysis of samples containing 7% (v/v) of methyl *tert*-butyl ether.

De la Guardia et al.[114] proposed a method for the flow injection FTIR spectrometric determination of methyl *tert*-butyl ether in unleaded gasoline. The method is based on the use of first-order derivative measurements in a flow system. The recovery of methyl *tert*-butyl ether in spiked natural samples varies from 98.2 to 102% and the relative standard deviation was 0.6% for samples containing 0.8% (v/v) methyl *tert*-butyl ether. Results obtained in the analysis of commercial gasoline samples compare well with those found by GC.

The determination of organic compounds in complex matrixes suffers from serious limitations owing to the overlapping of absorbance bands, which prevents direct determinations of a series of compounds and causes strong matrix interference.

The use of derivatives techniques in spectrometry has opened up new possibilities for the resolution of mixtures and compensation for matrix interference.[152–154,131]

Petrol is a complex mixture of volatile flammable liquid hydrocarbons containing hundreds of different natural components and some additives.

Gallignani et al.[9] proposed the simultaneous FA FTIR determination of benzene, toluene and methyl *tert*-butyl ether.

Kerosene is an important fuel for practical purposes. Under different names or with slightly different characteristics, refined kerosene is the selected fuel for civil and military use in jet-fuel turbine aircraft. Therefore it is an important task to assure the kerosene quality. The main kerosene physicochemical characteristics are covered the British Ministry of Defence specification[155] and/or the ASTM guides.[156] Both of them comprise a minimum of 26 tests to be carried out by refinery laboratories and/or external surveillance companies.

Several aircraft fuel quality properties like density, freezing point, flash point, aromatic content, initial boiling point, final boiling point and viscosity have been predicted from the FTIR spectra in the range 4000 to 600 cm^{-1}, using multivariate techniques. Multiple linear regression, PCR and PLS models have been tested. FTIR/PLS repeatability and reproducibility values fall well within the ASTM ranges and the standard error of prediction values is good. Sample manipulation was improved by using a stopped-flow system.[5]

5.3 Fourier Transform Infrared Determination of Industrial Products

Ethanol and also amylene are added to analytical reagent-grade chloroform as stabilizers in order to avoid the decomposition of this chlorinated solvent and the formation of phosgene.[157] The determination of ethanol in chloroform can be carried out by chromatography. However, IR spectrometry, in the near range, offers exciting possibilities for this type of analysis due to the transparency of chloroform and the presence of characteristic bands of ethanol in this region of the spectrum. In the last ten years, a big effort has been made in the development of on-line procedures for process monitoring, based on NIR measurements,[158–160] generally using a combination of chemometrics and fiber-optic probes. Working at a fixed wavelength[4] or using the stopped-flow approach, it is possible to develop the FIA/NIR procedure for a variety of aqueous[9] and nonaqueous[4] samples. López-Anreus et al.[160] propose a simple and direct FIA procedure for the determination of the stabilizing agent ethanol in chloroform samples. The procedure is based on the use of an absorbance band of ethanol in the NIR region at 2272 nm, measured in front of a reference sample of chloroform stabilized with amylene. The method developed provides a limit of detection of 0.0045% (v/v) and a dynamic range up to 10% (v/v). The variation coefficient of six independent analyses of a real sample containing approximately 1% (v/v) of ethanol was as low as 0.4%, while the injection frequency can reach 78 samples per hour.

Polymers are present in a large number of manufactured products and the quality of a polymer is established from different parameters: viscosity, end-group analyses, branching percentage, cross-linking degree, degree of crystallinity, density and molecular weight, which are characteristic of each lot.

Polymers have been investigated by MIR using transmission data[161] and also using NIR.[28] De la Guardia et al.[162] developed a simple procedure for the determination of some average properties of nonylphenol-ethylene oxide condensates, such as average molecular mass, average degree of condensation, the hydrophilic/lipophilic balance (HLB) and the percentage of ethylene oxide, which are characteristic of this kind of surfactant condensate. The method, based on the existence of a regression between the logarithm of the surfactant properties and the logarithm of the ratio of the peak heights of the bands at 960 and 840 cm^{-1}, is precise and accurate. Variation coefficients as low as 0.9% for HLB, 1% for ethylene oxide percentage and 1.6% for molecular mass were obtained.

For the determination of polymers and composite materials by IR, some of the limitations come from the use of extreme temperature and pressure conditions. However, recent developments, such as that proposed by Hanssen and Snail,[163] who developed a diffuse gold integrating sphere which can support up to 250 °C, and the off-the-shelf bidirectional reflectance accessories with controlled atmosphere, which can be used at 500 °C, offer new possibilities for operating in extreme experimental conditions.

5.4 Fourier Transform Infrared Determination of Products of the Paint Industries

Xylol, a solvent commonly used in the paint industry,[48,164,165] is a mixture of *o*-, *m*- and *p*-xylene. Garrigues and de la Guardia,[102] proposed a series of mathematical models for the FTIR determination of *o*-, *m*- and *p*-xylene in xylol without the need to use absorption cells with a known optical path length. The relative errors found in the analysis of binary mixtures are of the order of 1.4%, and those found for ternary mixtures are lower than 3% in most instances, for samples containing from 10 to 75% m/m of each component. In 1992, the same team proposed a FIA/FTIR method for the determination of xylene. The best limit of detection obtained was 0.01% (v/v). The relative standard deviation was 1% for a sample containing 0.4% of *o*-xylene in hexane.

Solvents are necessary in paint formulations in order to improve the solubility of resins and polymers and to improve the fluidity of the final product. Organic solvents traditionally employed in paint manufacture include carbonyl and aromatic compounds. However, the use of water as a paint solvent has always been attractive for reasons of low cost and absence of toxicity risks.[121] Water-borne paints need a minimum application temperature of 5 °C adequate film formation and, because of that, atmospheric conditions can delay its drying time. For this reason, these paints need the addition of a co-solvent at low concentrations; the butylglycol being one of the most commonly employed.[166]

The analysis of solvents employed in paint industry is usually carried out by GC.[167,168] However, this procedure is slow and time-consuming and not very appropriate for the direct analysis of aqueous samples. The use of FTIR allows the direct determination of butylglycol in water-borne paint solvents.[6] The method is based on the injection of 2 μL of untreated paint solvent into an electrically heated Pyrex glass reactor in which the sample is vaporized at 150 °C. The vapor phase generated is transported by means of a nitrogen carrier flow of 400 ml min^{-1} into an IR multiple pass gas cell and the spectrum in the MIR is recorded between 2500 and 600 cm^{-1} as a function of time. Data found for samples are interpolated in two calibration curves obtained by injecting different volumes of pure butylglycol and pure water. The measurement of the area of the flow injection recording obtained from the absorbance of the transient signals in the range 1137–1131 or 1071–1065 cm^{-1} for butylglycol and 1660–1640 cm^{-1} for water allows the direct determination of these two compounds in the same sample. The method provided relative standard deviation values around 1%, a limit of detection of the order of 2.7–4.5 ng, recovery percentage values from 96 to 104% and a sampling frequency of 65 h^{-1}.

Paint solvents generally contain aromatic and carbonyl compounds with a high volatility. In this sense, acetone is nowadays one of the most important solvents in the paint industry, owing to its high solvent power for a wide range of resins and its economic price. The combination between alcohols and acetone, in different proportions, improves its solvent power and, because of that, acetone and isopropanol mixtures are commonly used in nitrocellulose paint formulations.[165] Vapor generation FTIR provides a way for direct determination of acetone and isopropanol in nitrocellulose paints. Spectra were recorded between 2000 and 500 cm^{-1}. Data found for samples were interpolated in two calibration curves obtained by injecting different volumes of pure acetone and isopropanol. The measurement of the height and area of the flow injection recording obtained from the absorbance of the transient signals in the range of 1743–1737 cm^{-1} and 956–950 cm^{-1} allowed the direct quantification of the solvents. The limit of detection of the method was of the order of 0.5–3.9 ng, with a relative standard deviation from 0.09 to 2.8%. The solvent composition in a nitrocellulose paint can be determined by the aforementioned procedure after a

simple treatment consisting of sample dilution with CCl_4 followed by centrifugation at 4000 rpm for five minutes.[7]

A method has been developed for the direct simultaneous determination of *o*-, *m*- and *p*-xylene in xylol by FTIR.[7] The method is based on the injection of samples, diluted in hexane, into a carrier solution of hexane. The absorbance measurement, were carried out at 743, 770 and 796 cm^{-1}. The limit of detection corresponds to 0.03% v/v for *o*- and *m*-xylene and to 0.02% v/v for *p*-xylene, using a 0.13 mm path length micro flow cell.

5.5 Fourier Transform Infrared Determination of Products in the Field of Health

The determination of ethanol in blood is very important, especially in establishing responsibility in traffic accidents. The upper permissible concentration level of ethanol in blood for drivers depends on different national laws: for example, in France, the upper limit is 0.5 g of ethanol per litre of blood. The determination of ethanol in blood is usually carried out, after previous treatment, by headspace GC using a mass-spectrometric detector or a flame ionization detector, or by using a specific instrumentation. Recently, Pérez-Ponce et al.[115] show that this kind of determination can be carried out by FTIR through direct injection of samples in a vaporizer and measurement in the vapor phase, in order to avoid the interference of the sample matrix components. The measurements were made at 1050 cm^{-1} to increase the selectivity. This band corresponds to the C–O stretching vibration in ethanol and has been demonstrated to be useful for breath analysis.[169] The method is based on the injection of a discrete sample volume of 10 μL into an electrically heated Pyrex glass reactor. The ethanol is vaporized in the reactor at a temperature of 90 °C and introduced by means of a N_2 carrier flow inside a long-path IR gas cell. The corresponding FA is recorded as a function of time. With the transient signal obtained in the range 1150–950 cm^{-1}, it is possible to quantify ethanol up to 2 g L^{-1}, with a limit of detection of 0.02 g L^{-1}, and an analysis frequency of 40 samples per hour. This method can be applied to a single drop of finger blood.

IR spectrometry is very useful as a detector in liquid chromatography (LC) to solve complex analyses requiring simultaneous chromatographic and spectrometric discrimination, and provides additional qualitative information not available from conventional LC detector.[170–172]

FTIR spectrometric detection in LC can be accomplished in two ways: (i) on-line detection via the use of flow cells[173,174,228] and (ii) off-line detection after solvent removal.[175,176] The first approach is simpler, but presents limitations regarding excessive absorption caused by the carrier solvents and thus, in general, is less employed. The second approach eliminates the solvent problems but involves the use of expensive interfaces and, because of that, UV/VIS absorbance spectrometry or molecular fluorescence remains one of the most widely used spectrometric detection techniques in LC.[177]

LC has been employed for the analysis of oils and greases, providing a good way of determining fatty acids and triglycerides.[178–180] In some studies, FTIR spectrometry has been employed for the determination of triglycerides, in both normal and reversed-phase,[181] estolide triglycerides,[182] free acids and partial glycerides.[183]

Sterols are the main constituents of the unsaponifiable matter and represent an important group of minor components of oils and greases. Stearic acid, cholesterol and cholesteryl palmitate have been separated in less than 14 min by LC coupled with FTIR spectrometry.[184] General detection was carried out at 2868 or 2855 cm^{-1} and selective detection at 3285 cm^{-1} for stearic acid and 3526 cm^{-1} for cholesterol. In all cases, a baseline was established at 3900 cm^{-1}. The method was validated by application to the determination of cholesterol in animal greases and fish oils. Samples that have previously undergone saponification with KOH were extracted with petroleum ether, redissolved in chloroform and the final solution injected into the chromatographic system. The recoveries were 95–99% for samples spiked with cholesterol and 100–102% for samples spiked with cholesteryl palmitate.

Methanol, originally obtained by the destructive distillation of wood, is nowadays usually manufactured from hydrogen and carbon monoxide or carbon dioxide and also by the oxidation of hydrocarbons. These methods of manufacture and the low taxes imposed on this alcohol, as compared with those on ethanol, make methanol a cheap and dangerous substitute for ethanol. The ingestion, inhalation or skin absorption of methanol can lead to anything from headaches to blindness and even death (the latter from ingestion of 100–200 mL). Therefore, (the latter) analytical control in both beverages and cosmetics is necessary. Colorimetry, GC and immersion refractometry are the three methods recommended by the Official Methods of Analysis of the Association of Official Analytical Chemists (AOAC)[185] for methanol determination in beverages. However, all these methods need the previous treatment of samples, which is, in general, tedious and time-consuming. IR spectrometry has been employed in the identification or quantification of methanol in a series of different samples. Open path FTIR can be employed for qualitative monitoring of methanol vapor in the atmosphere.[186] Quantitative methods have also been proposed for the NIR second derivative determination of methanol in synthetic mixtures of methanol, butanol, acetone, methylene chloride and dichloropropane.[187]

Similarly, methods were proposed for FTIR determination of mixtures of 2,2-dimethoxypropane, acetone and methanol,[188] which is especially useful in the simplex optimization for FTIR remote sensing measurement of SF_6, methanol, acetone and 2-butanone in synthetic mixtures.[189]

For the analysis of real samples, optical fiber NIR spectrometry was used for methanol determination in gasoline.[190] IR gas-filter correlation spectrometry was employed to measure methanol in vehicle exhaust.[191] FTIR was employed for the remote analysis of CO, CO_2 and methanol in motorboat exhausts.[192]

The determination of methanol in the presence of ethanol can be carried out by GC[193–195] and also by GC/FTIR and mass spectrometry (MS).[196] The IR emission from a flame has been also proposed as a means of detection for LC to analyze mixtures of methanol, ethanol and propanol.[197]

The filtering correlation function "*compare*" from Perkin Elmer has been proposed for the discrimination of spectra of mixtures of methanol and ethanol,[198] and thermal lens spectrometry has been employed for the partial quantitative determination of methanol and ethanol in gaseous samples.[199]

Kuehl and Crocombe[200] have established a model for the quantitative analysis of methanol, ethanol and acetone in fermentation broth, showing that by using an ATR cell, synthetic mixtures of the three compounds under study can be analyzed with relative errors below 2%.

Garrigues et al.[201] proposed a FTIR procedure for the direct determination of methanol and ethanol in liquid samples such as alcoholic beverages and eau-de-Cologne. It is based on vapor generation from small injected volumes of untreated samples into a heated Pyrex glass reactor in which ethanol and methanol are volatilized, at a temperature of 80 °C, and introduced into a long-path IR gas cell by means of a N_2 carrier flow. The spectra obtained present two characteristic ethanol bands (1050 and 880 cm^{-1}) and a single characteristic methanol band (1030 cm^{-1}). The measurement of the area of the transient recording obtained for the wavenumber ranges 1025–950 and 950–820 cm^{-1} allows the determination of ethanol and methanol in the same sample by using a simple proportional equation approach. The limit of detection values found for an injection volume of 1 μL were 0.21% v/v for ethanol and 0.04% for methanol, and the relative standard deviation values were between 0.5 and 1.4% for five analyses of samples containing between 30–80% (v/v) ethanol and 0.5–3.5% (v/v) methanol. Acetone, ethyl acetate, 1-propanol and 2-propanol do not interfere with this determination when they are present at concentration levels of the order of those of methanol.

5.6 Fourier Transform Infrared Determination of Compounds in the Natural Environment

The standard protocol for oil and grease determination in polluted waters is a gravimetric procedure based on a liquid–liquid extraction (LLE) with Freon 113.[202] The pioneering studies on IR spectrometric determination of oil and grease in waters were based on CCl_4 extraction.[203] However, the quantitative extraction of all types of oils like hydrocarbons, vegetable oils, animals fats, waxes, soaps, greases and related matter is difficult. Serious problems have been reported for the total extraction of several materials from waters, including gasoline, for which extraction yields of about 50% were found.[204] The use of chlorinated hydrocarbons, like freon and CCl_4, is undesirable because of their ozone-layer depleting effect.[205] Thus it is an urgent task to search for alternative procedures for oil and grease extraction from waters.[206,207]

The use of microwave ovens offers a fast way of improving analytical procedures that include a thermal step. Microwave-assisted procedures have being developed for sample digestion[208] and derivatization.[209] More recently, the use of a microwave-assisted technology has been proposed for the extraction of organic pollutants from sediments for their subsequent analysis by chromatography.[210,211]

In 1997, Daghbouche et al.[184] evaluated LLE, solid phase extraction and microwave-assisted extraction for FTIR spectrometric determination of oil and grease in polluted waters. A fast microwave-assisted quantitative procedure was proposed for the total extraction of oil and grease into CCl_4 from water samples, with an irradiation time of 1 min, at an exit power of 520 W, using closed polytetrafluoroethylene (PTFE) vessels. The FTIR quantification of oils was carried out by the measurement of the area under the absorbance spectra in the range between 3058 and 2780 cm^{-1}, using a baseline established between 3200 and 2700 cm^{-1}. The analytical features of the method and those of LLE/FTIR spectrometry were evaluated and samples spiked with different types of oils examined.

The environmental impact of laboratory practices is not insignificant. Large amounts of toxic compounds are produced every day in research and application laboratories. The storage and destruction of dangerous pollutants contained in laboratory wastes needs adequate decontamination plants, and thus the elimination of waste is expensive and involves strict safety requirements. So it is necessary to substitute traditional methods by clean analytical technologies.[212] FIA provides an interesting way to achieve reduction of reagent consumption and wastes. Using FIA/FTIR it is possible to offer an alternative to the traditional methods, providing a

drastic reduction of pollutant side effects. A semi-micro distillation unit was therefore incorporated into a simple FIA/FTIR manifold for the on-line recovery of the solvent used as carrier. This system was applied to the direct, simple and fast determination of ketoprofen,[124] a nonsteroid anti-inflammatory drug with analgesic and antipyretic properties.[213] The system permits a drastic reduction of reagent consumption and easy and fast sampling and cleaning of the measurement cell, as compared with the official method in the British Pharmacopoeia for ketoprofen determination, which is based on the measurement of the absorbance at 250 nm using methanol as solvent.[214] For the quantification of ketoprofen in pharmaceuticals, the carbonyl bands at $1712\,cm^{-1}$ and $1666\,cm^{-1}$ were employed and the developed method provides a limit of detection of $0.04\,mg\,ml^{-1}$ (3s) and a dynamic range which extends up to $10\,mg\,ml^{-1}$. Typical coefficient of variation values ranged between 1.6 and 3%, with a sample injection frequency greater that 42 per hour. Accurate and precise results were obtained in the analysis of real pharmaceutical samples.

Another example of an important reduction in the side effects of analytical procedures is given by the quantification method of raw sugarcane sugars proposed by Cadet et al.,[98] which avoids the previous clarification of samples required by usual methods of sugar determination (HPLC, polarimetry, GC). This step of clarification needs a large quantity of lead acetate, a strong pollutant which, when released into the environment can pollute surface waters.

There are several methods proposed for the determination of carbonate and bicarbonate in waters, based on both instrumental and volumetric procedures. The official method is based on a simple titrimetric procedure, but a series of problems have been reported with the end-point determination and evaluation of titration data.[185]

There are only few precedents for the IR determination of inorganic carbon in water by batch and FIA. One of these is that proposed for seawater analysis, based on batch acidification with H_3PO_4 and colorimetric or IR determination of CO_2 stripped with N_2.[215] Another is based on the use of a patent cylindrical thin-film reactor with an actively rotating inner cylinder and a central low-pressure mercury lamp. This allows the decomposition of the organic molecules through UV radiation and that of inorganic carbonates by acidification. The release of the CO_2 is carried out by a N_2 flow and its determination is done by IR.[216] More recently, Pérez-Ponce et al.[217] proposed the use of an electrically heated gas-permeation unit (GPU) for the vapor-generation FTIR of total carbonate in waters. The developed method is based on the simultaneous injection of 100 μL of sample and 100 μL of nitric acid in a two-channel manifold with a merging zone. This zone provides the generation of CO_2 through the GPU, heated at 90 °C, from which a stream of N_2 sweeps the CO_2 to a long-path IR gas cell. Absorbance measurements were made in the range from 2500 to $2150\,cm^{-1}$ and the corresponding flow injection recordings were obtained as a function of time. The method provides a limit of detection of 4.6 ppm (expressed as mg of $HCO_3^-\,L^{-1}$) and a sampling frequency of $30\,h^{-1}$. Results obtained for a series of natural waters compare well with those obtained by a titrimetric reference method.

More recently, these authors[14] proposed a microwave-assisted vapor-generation FTIR spectrometric procedure for the determination of total carbonate in waters. The method is based on the simultaneous injection of 100 μL of sample and 300 μL of 0.1 M nitric acid into a two-channel manifold with a merging zone; a coil located inside a microwave oven favors the removal of CO_2. The carbon dioxide is separated from the distilled water employed as a carrier, by means of gas–liquid separator, and is introduced by a nitrogen carrier flow inside a long-path IR absorption gas cell. This provides direct quantification of total carbonate concentration in the range up to 1000 mg $HCO_3^-\,L^{-1}$ with a sampling frequency of 15 samples per hour. The procedure has a limit of detection of 15 mg $HCO_3^-\,L^{-1}$ and a variation coefficient of 1.3% for five independent analyses.

5.7 Quantitative Fourier Transform Infrared Analysis of Compounds at Trace Levels

The use of FTIR for trace analysis is problematic, due to the lack of sensitivity of this technique and the use of small path length values. Substantial efforts were undertaken in order to improve the limit of detection of FTIR, e.g. by using alternative approaches such as the stopped-flow technique.[11,133] Nevertheless they do not provide adequate solutions. Therefore other strategies have been investigated to increase the sensitivity of IR determinations.

The excellent results obtained by on-line preparative concentration of metallic elements by FA and atomic spectrometric techniques[218] offers a model strategy for the improvement of the sensitivity of FTIR determinations. As an example for the determination of pesticides in waters, solid-phase extraction offers an excellent way for improving the limit of detection of FTIR. This strategy was selected because it allows easy on-line preparative concentration and does not require high volumes of organic solvents or the use of complicated phase-separation manifolds.[219–221] Garrigues et al.[138] proposed a new method for the FTIR determination of carbaryl, a pesticide found in natural waters which was

determined at 1746 cm^{-1}. Their procedure permits (i) in-field sampling, (ii) stabilization of pesticides and (iii) fast determination of carbaryl. The sensitivity obtained with this procedure corresponds to 0.044 area units $\mu g^{-1}\,cm^{-1}$ and with a limit of detection 15 $\mu g\,L^{-1}$ of carbaryl, using C18 cartridges for preparative concentration and dichloromethane for on-line elution. The method could be applied to other types of components, providing new possibilities for the application of FTIR to trace analysis.

5.8 Other Fourier Transform Infrared Coupled Methods

SIA was introduced in 1990 by Ruzicka and Marshall[222] and has improved classical FIA in many ways, especially concerning the drastic reduction of reagent consumed and waste generated and the robustness of the resulting analysis system. In classical FIA, the generation of different injection sequences would require a physical rearrangement of the FIA manifold for each sequence. This situation is different in the case of SIA, where only changes in the controlling software are required to create different interpenetrating dispersion profiles between samples and reagents. Schindler et al.[171] employed for the simultaneous determination of glucose, fructose and sucrose in aqueous standards as well as in soft drinks using FTIR detection and multivariate PLS data analysis. Obtained results were compared with those found by an external reference method. Typical deviations from the results were of the order of 2.5%, 4.1% and 2.1% for glucose, fructose and sucrose respectively (Figure 10).

Vonach et al.[135] proposed the modulation of the pH as a novel approach for the determination of phosphate with FIA and FTIR detection.

Figure 10 SIA/FTIR manifold: holding coil, 0.5 mm i.d., 250 cm; S1-3, standard solutions; W, water; mixing coil, 0.3 mm i.d., 30 cm. (Reproduced with permission from Lendl et al., *Analytical Chemistry*, **69**(15), 2877–2881, © 1997, American Chemical Society.[226])

The use of FTIR as a detection system in HPLC is of particular interest in analytical chemistry. In particular, the fingerprint region around 1400–900 cm^{-1} provides valuable data for the confirmation of molecule structures, since most organic (and many inorganic) compounds exhibit strong and narrow absorption bands, providing a high degree of qualitative and structural information.

As has been indicated in previous sections, the coupling of HPLC and FTIR can be performed by using a standard flow cell, without mobile phase separation and by introducing an interface that evaporates the eluent and deposits the analytes into a medium compatible with FTIR detection. Another approach for solvent elimination, which is particularly interesting for aqueous solutions, is based on post-column on-line extraction. After extraction with chlorinated solvents (CH_2Cl_2, $CHCl_3$, CCl_4), various interfaces can be applied; regular flow cells;[223,224] loading of the extracts on KBr, with subsequent DRIFT detection;[225] or, more recently, deposition on a zinc selenide window by a spray jet assembly, followed by the analysis of the residues with a FTIR-microscope.[176]

Vonach et al.[135] used FTIR as a molecular-specific detection system for HPLC in an aqueous phase, and developed a method for sugar determination in beverages. The separation was achieved with an isocratic HPLC set-up using an ion exchange column. The FTIR detection of the C–O bands in MIR, between 1000 and 1200 cm^{-1}, was performed in real time with a 25 ml flow cell without elimination of solvent. Characteristic FTIR spectra of sucrose, glucose and fructose were recorded during the separation. The calibration of these sugars in the 5–100 $mg\,mL^{-1}$ range resulted in a linear correlation with a standard deviation of the method of 0.11, 0.07 and 0.11 for sucrose, glucose and fructose respectively. The method was found also to be suitable for the identification and the quantification of minor components in beverages, such as taurine (4 $mg\,mL^{-1}$) and ethanol (0.4 $mg\,mL^{-1}$).

Lendl et al. in 1997[226] developed a flow system containing a micromachined lamella-type porous silicon reaction and a novel MIR fiber-optic flow cell, which was used for the enzymatic determination of sucrose in aqueous solutions. The method relies on the enzymatic hydrolysis of sucrose catalysed by β-fructosidase and on the acquisition of FTIR spectra before and after complete reaction. The enzyme was covalently bound to the porous silicon reactor in a HF/ethanol mixture. For the measurement of small amounts of aqueous solution, a miniaturized flow cell was developed which consisted of two $AgCl_xBr_{1-x}$ fiber tips (0.75 mm diameter) coaxially mounted in a PTFE block at a distance of 23 mm. The flowing stream was directed through the gap between the two fiber tips, which served to define the optical path length and to bring the focused MIR radiation to

Figure 11 (a) Manifold used for the FTIR detection in miniaturized total analysis systems for sucrose analysis. (b) Sketch of the developed miniaturized fiber-optic flow cell allowing for the acquisition of a FTIR spectrum of 10 nL. The diameter of the AgC_xIBr_{1-x} was 750 mm. (Reproduced with permission from Lendl et al., *Analytical Chemistry*, **69**(15), 2877–2881, © 1997, American Chemical Society.[226])

the place of measurement. Using this set-up, a probed volume of about 10 nL was obtained. The calibration curve was linear up to 10 $mmol^{-1}$ sucrose. Furthermore, the potential of this method was demonstrated by the analysis of binary sucrose/glucose mixtures showing no interference from glucose, and by the successful determination of sucrose in real samples (Figure 11).

The introduction of FTIR as a detector in miniaturized total analysis systems represents a significant step towards the development of techniques capable of obtaining molecular-specific information in miniaturized flowing streams. The huge amount of chemical information contained in FTIR spectra was exploited to reduce the number of enzymatic reactions needed for the determination of sucrose in aqueous standards as well as in real samples such as soft drinks. Both the development of a new molecular specific detector based on a miniaturized IR fiber optic flow cell and the application of a silicon microreactor with in-situ fabricated porous silicon layers as a surface-enlarging matrix for immobilized enzymes, can be considered as some of the most interesting uses of FTIR.

6 LIMITATIONS AND PERSPECTIVES OF INFRARED SPECTROSCOPY FOR QUANTITATIVE ANALYSIS

IR is probably the most significant range of the spectrum in order to provide an appropriate identification of a molecule and, because of that, IR spectrometry has been widely employed to confirm the nature of compounds and particularly to evaluate pure products.

However, the high absorption of IR radiation by water and the presence of a large number of characteristic bands for each functional group inside a molecule decreases sensitivity (notably with the use of small band-pass cells) and selectivity. These problems must be solved in order to obtain accurate quantitative data.

In addition to the pioneering studies carried out during the 1950s, the new age of quantitative analysis through IR spectrometry is based on two important developments in the field of analytical chemistry: chemometrics and FA.

Chemometrics has provided the mathematical tools to solve overlapping problems, which can be found in the interpretation of spectra in NIR and MIR, and to solve the serious problems presented by the influence of the sample environment in both the size and shape of the characteristic bands of analytes. As has been discussed in section 2, the use of multivariate calibration strategies, and specially PCR and PLS, provides the best way to solve these kinds of problems. It offers exciting possibilities for multicomponent determinations, through the use of a reduced number of previously analyzed samples as a calibration set and the prediction of sample concentrations. Through PCR and PLS data treatment it is possible to obtain accurate data for the concentration of several analytes in the same sample and also an estimation of physical properties.

The second milestone in the recent development of quantitative analysis by IR is the use of FA strategies, which improves sample introduction and method automation, and also reduces drastically the side effects of the use of IR-transparent solvents, which are frequently toxic. However, the main contribution of FA to the improvement of quantitative determinations by IR are the possibilities offered by the on-line coupling of derivatization procedures and especially for the on-line preparative concentration and elution of analytes. This increases drastically the limit of detection of the analytical procedures and offers an easy way to solve the problem of some matrix or intermolecular interference.

In the next few years there is expected to be a significant growth of the scientific literature on quantitative methods of determination by IR, both for trace analysis and for the screening of the main components of foods, biological and environmental samples. In this sense the new generation of low-cost FTIR instruments configured for NIR, MIR and FIR, and the development of new methodologies for direct sample analysis, will have a synergistic effect on the use of IR as a tool for routine analysis.

New developments in the remote sensing of air pollutants and recent advances in new strategies for enzymatic analysis and vapor generation-FTIR will be generalized in the following years. This will be achieved through the (i) introduction of fast and robust standardization methodologies, (ii) the use of enzymes in nonaqueous systems and (iii) the on-line treatment of solid samples for a fast screening of volatile organic compounds.

In short, we are at the beginning of a new area of vibrational spectrometry, which will clearly evidence and explore the possibilities of IR for quantitative determination of major, minor and trace components by incorporating the advances in chemometrics and automation.

Spectral Data, Modern Classification Methods for

Yvette L. Mallet and Danny H. Coomans
James Cook University, Townsville, Australia

Olivier de Vel
DSTO, Salisbury, Australia

1 Introduction **1**
2 Classification Methods **2**
2.1 Bayesian Quadratic Discriminant Analysis 2
2.2 Bayesian Linear Discriminant Analysis 3
2.3 Regularized Discriminant Analysis 3
2.4 Fisher's Linear Discriminant Analysis 3
2.5 Flexible Discriminant Analysis 4
2.6 Penalized Discriminant Analysis 4
3 Feature Extraction **4**
3.1 Feature Selection 4

A major concern which arises from the classification of spectral data, such as near-infrared (NIR) spectra, is that the number of variables often exceeds the number of cases. In this instance each spectrum represents a case or observation, and each variable corresponds to the wavelengths at which a response (e.g. reflectance) is measured. Classification refers to the process of assigning a spectrum whose class identity is unknown into one of several predefined classes. There are two main strategies for combating the high-dimensional (i.e. more variables than cases) scenario. One strategy is to use a high-dimensional classifier, that is, one which is suited to the ill-posed nature of the data. The second strategy is to reduce the number of variables by a feature extraction method and supply the variables to a low-dimensional classifier, one which is suited to high observation-to-variable ratios. This article presents two high-dimensional classification methods – regularized discriminant analysis (RDA) and penalized discriminant analysis (PDA). The low-dimensional classifiers used include Bayesian linear discriminant analysis (BLDA), Bayesian quadratic discriminant analysis (BQDA), RDA and flexible discriminant analysis (FDA). Common stepwise selection routines are employed to investigate the effectiveness of the wavelet transform as a feature extraction technique. This includes implementation of the local discriminant bases (LDBs) algorithm and the adaptive wavelet algorithm (AWA).

1 INTRODUCTION

In this paper we investigate several strategies for classifying spectral data where the dimensionality or number of variables far exceeds the number of samples or objects. Such poorly posed data lead to a deterioration in performance of many standard classification techniques.[1] The presence of correlated variables can lead to a further deterioration in classification performance. Correlated data often result if the same response is measured at regular intervals in time or space. Although the techniques discussed in this paper can be applied to most highly correlated and highly dimensional data, such as time-varying signals, spectra and images, we focus our applications on the classification of NIR spectral data.

The discriminant problem when applied to NIR spectral data involves assigning an NIR spectrum whose class identity is unknown (Figure 1d) into one of the several predefined categories or classes. Figures 1(a), (b) and (c) show five sampled spectra from three different species of seagrass – *Halophila ovalis, Halodule uninervis/pinifolia* and *Halophila spinulosa*. The different species, which are referred to as species 1, 2 and 3 respectively, form the different group categories. A simple approach is to look for similarities between the unidentified spectrum and the spectra whose class identities are known. In this particular case this task is not straightforward, since the spectra from the different classes share similar characteristics. This problem highlights the relevance of automated discriminant methods for analyzing spectral data.

The general discriminant problem[2,3] can be expressed as assigning a spectra, represented by the p-dimensional vector $\mathbf{x}_i = (x_{1i}, \ldots, x_{pi})^T$, into one of $r \in \{1, \ldots, R\}$ classes. The assignment is performed by building a

Figure 1 Sample spectra from three species of seagrass. (a) Species 1 (*Halophila ovalis*); (b) species 2 (*Halodule uninervis/pinifolia*); (c) species 3 (*Halophila spinulosa*); (d) spectrum to be identified as species 1, 2 or 3.

discriminant model, using n training spectra where there are n_r spectra $\{\mathbf{x}_{i(r)}\}_{i=1}^{n_r}$ from each class r. The total, $n = \sum_{r=1}^{R} n_r$ training spectra are stored as columns in the $p \times n$ training data matrix $\mathbf{X} = (\mathrm{x}_1, \ldots, \mathrm{x}_n)$. Usually, $p \gg n$ for spectral data.

Several different discriminant or classification models exist. These are divided into two main groups – low- and high-dimensional classifiers. High-dimensional classifiers can be applied to data sets with low observation-to-variable (n/p) ratios. Conversely, low-dimensional classifiers are more suited to data containing high observation-to-variable ratios. The high-dimensional classifiers applied in this paper are PDA and, RDA. The low-dimensional classifiers applied are BLDA and BQDA, and FDA. These methods will be discussed briefly in section 2. For a more detailed account of these techniques the reader is referred to Mallet et al.[4]

If a low-dimensional classifier is to be used in a situation where there are many more variables than objects, then it is recommended that some form of data reduction or feature extraction be implemented. Feature extraction involves selecting a smaller subset of variables. Selection can be from the original set of variables or from a set of transformed variables. Principal components are common examples of transformed variables. Another set of transformed variables that remains relatively unexplored is wavelet coefficients.[5] In this paper we investigate the potential of wavelet coefficients as features for discriminant analysis. Wavelet-based feature extraction methods involve two main procedures. The first procedure is the application of the discrete wavelet transform (DWT) to obtain the wavelet coefficients. The second procedure is the selection of a subset of wavelet coefficients to be supplied to the classification model. Wavelet coefficients are considered useful because they can analyze different segments of data at different resolutions, thus enabling localized features in the spectra to be detected. These features can be extremely useful for discriminating purposes. Previous applications of wavelet-based feature extraction methods for classifying data are available.[4,6–12]

The goal of this paper is not necessarily to find the best discriminant strategy, but to review some traditional methodologies and introduce the reader to some modern classification techniques, which have been divided into two groups:

1. classification of all the original data using a high-dimensional classifier
2. classification using a low-dimensional classifier where features are extracted from either the original data, or the DWT.

The paper proceeds by introducing the low- and high-dimensional classifiers in section 2. Section 3 discusses some feature extraction procedures and section 4 describes the DWT. Section 5 applies the different classification applications to four spectral data sets which exhibit different characteristics. Section 6 summarizes the classification results. Section 7 presents some guidelines for choosing classification techniques and concludes with some final remarks.

2 CLASSIFICATION METHODS

This section briefly describes the discriminant methods that were mentioned in section 1. The classifiers based on Bayes's method are introduced first, followed by a description of the classifiers based on Fisher's linear discriminant analysis (FLDA). Although FLDA is not applied in this article, the method is briefly reviewed as it is the foundation for FDA and PDA.

2.1 Bayesian Quadratic Discriminant Analysis

Bayes's rule assigns a spectrum $\mathbf{x}$ to the class $r \in \{1, \ldots, R\}$, which maximizes the posterior probability,

as shown in Equation (1).

$$P(r|\mathbf{x}) = \frac{p(\mathbf{x}|r)P(r)}{\sum_{r=1}^{R} p(\mathbf{x}|r)P(r)} \quad \text{for } r = \{1, \ldots, R\} \tag{1}$$

Here, $P(r)$ is the prior probability of belonging to class r, and $p(\mathbf{x}|r)$ are the class probability densities, i.e. the probability of spectrum $\mathbf{x}$ arising from group r. BQDA[2,3] assumes that the class probability densities follow a multivariate normal distribution as shown in Equation (2),

$$p(\mathbf{x}|r) = (2\pi)^{-p/2}|\mathbf{S}_r|^{-1/2}\exp[-0.5(\mathbf{x} - \bar{\mathbf{x}}_r)^T\mathbf{S}_r^{-1}(\mathbf{x} - \bar{\mathbf{x}}_r)] \tag{2}$$

where $\mathbf{S}_r = \sum_{i=1}^{n_r}(\mathbf{x}_{i(r)} - \bar{\mathbf{x}}_r)(\mathbf{x}_{i(r)} - \bar{\mathbf{x}}_r)^T/n_r$ is the covariance matrix of class r, and $\bar{\mathbf{x}}_r = \sum_{i=1}^{n_r}\mathbf{x}_{i(r)}/n_r$ is the mean vector of class r. Both $\mathbf{S}_r$ and $\bar{\mathbf{x}}_r$ are sample estimates of the population class covariance matrices and mean vectors, respectively.

2.2 Bayesian Linear Discriminant Analysis

As with BQDA, BLDA[2,3] also assumes that the class probability densities follow a multivariate normal distribution. BLDA makes the added assumption that the class covariance matrices in Equation (2) are equal, and are replaced with a pooled covariance matrix $\mathbf{S}_{\text{pooled}} = \sum_{r=1}^{R} n_r\mathbf{S}_r/n$ to give Equation (3).

$$p(\mathbf{x}|r) = (2\pi)^{-p/2}|\mathbf{S}_{\text{pooled}}|^{-1/2} \times \exp[-0.5(\mathbf{x} - \bar{\mathbf{x}}_r)^T\mathbf{S}_{\text{pooled}}^{-1}(\mathbf{x} - \bar{\mathbf{x}}_r)] \tag{3}$$

2.3 Regularized Discriminant Analysis

When the observation-to-variable ratio is small (e.g. less than three) the estimates of the class covariance matrices $\mathbf{S}_r$ become highly variable.[6]

This can cause serious problems in the performance of the classification procedure. To overcome this phenomenon, Friedman[6] has proposed one method of regularizing the class covariance matrix. RDA uses a similar classification rule to that shown in Equation (2) for BQDA. Instead of using the unbiased estimate of the class covariance matrix, RDA replaces $\mathbf{S}_r$ in Equation (2) with the regularized covariance matrix $\mathbf{S}_r(\lambda, \gamma)$ which undergoes a two-stage regularization procedure. Despite the possibility of slightly increasing bias, regularization can produce dramatic improvements in classification.[1,6]

The first regularization procedure replaces the class covariance matrix with a linear combination of the class and pooled covariance matrices, as shown in Equation (4).

$$\mathbf{S}_r(\lambda) = (1 - \lambda)\mathbf{S}_r + \lambda\mathbf{S}_{\text{pooled}} \tag{4}$$

The parameter $\lambda \in [0, 1]$ controls the degree to which the pooled covariance matrix should be used. This form of regularization is similar to that which occurs when reverting from BQDA to BLDA. Replacing the class covariance matrix with the pooled covariance matrix reduces the number of parameters that have to be estimated. In fact, if $\lambda = 1$ then $\mathbf{S}_r(1) = \mathbf{S}_{\text{pooled}}$.

The second regularization procedure is shown in Equation (5).

$$\mathbf{S}_r(\lambda, \gamma) = (1 - \gamma)\mathbf{S}_r(\lambda) + \frac{\gamma}{d}\text{trace}[\mathbf{S}_r(\lambda)]\mathbf{I} \tag{5}$$

$\mathbf{S}_r(\lambda)$ is adjusted by scaling the covariance matrices towards a multiplier of the identity matrix $\mathbf{I}$. The value of $\gamma \in [0, 1]$ determines the degree to which $\mathbf{S}_{(r)}(\lambda)$ is shrunk towards a multiplier of the identity matrix. Different λ and γ values ranging between 0 and 1 are trialled. The pair of values which produces the minimal risk of misclassification is used.

2.4 Fisher's Linear Discriminant Analysis

Many pattern recognition methods are Bayesian- or Fisher-based techniques. The classifiers BLDA, BQDA and RDA are examples of Bayesian-based classifiers. Fisher-based classifiers stem from the time-honoured technique called FLDA. FDA and PDA, which are discussed in sections 2.5 and 2.6, respectively, are largely derived from FLDA.

As shown in Equation (6) FLDA assigns an object $\mathbf{x}$, to the class $r \in \{1, \ldots, R\}$ which minimizes

$$\|\mathbf{x}^T\mathbf{V} - \bar{\mathbf{x}}_r^T\mathbf{V}\|^2 \tag{6}$$

where $\mathbf{V}$ is a $p \times s$ matrix whose ith column is the eigenvector $\mathbf{v}_i$ which corresponds to the ith largest eigenvalue of $\mathbf{S}_W^{-1}\mathbf{S}_B$, and $s \leq \min(R - 1, p)$. Here, $\mathbf{S}_B$ and $\mathbf{S}_W$ are the between- and within-covariance matrices of the data matrix $\mathbf{X}$, respectively. These are calculated from the training data using the definitions in Equations (7) and (8).

$$\mathbf{S}_B = \frac{1}{n}\sum_{r=1}^{R} n_r(\bar{\mathbf{x}}_r - \bar{\mathbf{x}})(\bar{\mathbf{x}}_r - \bar{\mathbf{x}})^T \tag{7}$$

$$\mathbf{S}_W = \frac{1}{n}\sum_{r=1}^{R}\sum_{i=1}^{n_r}(\mathbf{x}_{i(r)} - \bar{\mathbf{x}}_r)(\mathbf{x}_{i(r)} - \bar{\mathbf{x}}_r)^T \tag{8}$$

The solution for $\mathbf{V}$ arises from the formal discriminant problem as shown in Equation (9)

$$\max \mathbf{v}^T\mathbf{S}_B\mathbf{v} \tag{9}$$

subject to the constraint shown in Equation (10).

$$\mathbf{v}^T\mathbf{S}_W\mathbf{v} = 1 \tag{10}$$

2.5 Flexible Discriminant Analysis

FDA[7] is a nonlinear extension of FLDA which incorporates nonparametric regression methods to obtain nonlinear decision boundaries. The method of FDA is quite involved. For this reason we provide a very descriptive review of the method and refer the reader to Hastie et al.[7] and Mallet[8] for more refined details.

FLDA produces linear decision boundaries for separating objects from different classes. One way of producing nonlinear decision boundaries would be to expand the predictor matrix so that it includes quadratic and bilinear terms.[7] This would have the effect of producing discriminant boundaries which exhibit quadratic characteristics. A much more sophisticated approach is used by FDA to obtain much more flexible decision boundaries than quadratic forms.

The nonlinear decision boundaries in FDA are obtained by adaptively computing an expanded set of predictor variables by using nonparametric regression methods such as MARS (multivariate adaptive regression splines)[9] and bruto.[10] The new independent variables are computed with the aim of predicting the columns of a class indicator matrix. Hastie et al.[7] show that the regression coefficients are, by means of a linear transformation, equivalent to the matrix of eigenvectors ($\mathbf{V}$) from FLDA. This relationship is neatly established by using optimal scoring as the link between regression analysis and FLDA (see also Breiman and Ihaka[11]).

2.6 Penalized Discriminant Analysis

PDA[12] follows a similar methodology to that used for FDA. That is, optimal scoring provides the link between regression and classification. The difference between FDA and PDA is in the regression method used. For FDA, the goal is to cater for situations where there is a high observation-to-variable ratio, and to produce flexible decision boundaries for classification. This is achieved by using adaptive regression methods such as MARS and bruto. The goal of PDA is to cater for situations where there is a low observation-to-variable ratio, and also for data containing large amounts of highly correlated variables such as spectra, signals and images. It becomes obvious that the regression methods used by PDA will differ from the regression methods used by FDA. The regression methods for PDA need to be suited to extreme dimensionalities and be somewhat resistant to multicollinearities. Consequently, PDA uses penalized least squares regression (PLSR) methods. Ridge regression[13] can be seen as a trivial PLSR method.

The use of penalized regression methods can be made equivalent to a penalized discriminant method by solving Equation (9) subject to the constraint

$$\mathbf{v}^T(\mathbf{S}_W + \mathbf{\Omega})\mathbf{v} = 1$$

where $\mathbf{\Omega}$ is a penalty matrix which helps prevent overfitting and other computational instabilities.

3 FEATURE EXTRACTION

Feature extraction[2,3] is a dimensionality reduction procedure that selects a subset of p_* variables from a much larger set of p variables. Typically, the dimensionality p_* of the subset of feature variables is less than p, and usually very much less than the number of observations, n. The main goal of feature extraction relative to this article is to extract as much relevant discriminatory information from the data as possible, while simultaneously eliminating redundant features which do not contribute to or have an adverse effect on the classification procedure. It is recommended that some form of feature extraction be implemented prior to the application of low-dimensional pattern classification methods.

The feature extraction procedure may involve selecting features from either the original (untransformed) data, or from data which has been transformed. Hence, feature extraction can consist of two main components – feature selection and feature transformation. These topics are explained in sections 3.1 and 3.2 respectively.

3.1 Feature Selection

Feature selection procedures select a subset of features or variables from the data. Features can be selected from the original data, also referred to as a variable selection, or from data which have been preprocessed or transformed in some other way. When feature selection is from the original data, the feature transformation is via the identity matrix.

One commonly used feature selection criterion for classication is the ratio of the between-to-within variability.[14] That is, for each variable, the between-variability divided by the within-variability is calculated and the variables that produce large values of this quotient are selected, and used as input to the classifier. This measure of between-to-within-variability is referred to as Fisher's criterion.[15] Other feature selection criteria commonly used include the Mahalanobis distance and Wilk's lambda.[16]

One criterion which is applied later in this article is the quadratic probability measure (QPM).[17] Since the QPM is a probabilistic measure, $0 \leq \text{QPM} \leq 1$. Ideally, larger values of the QPM are preferred, since this suggests that the classes can be differentiated with a higher

degree of certainty. The QPM is formulated as shown in Equation (11)

$$\text{QPM} = \frac{1}{n}\sum_{i=1}^{n} a_Q(i) \tag{11}$$

where $a_Q(i)$ is defined as shown in Equation (12).

$$a_Q(i) = \frac{1}{2} + P(r|\mathbf{x}_{i(r)}) - \frac{1}{2}\sum_{r=1}^{R} P(r|\mathbf{x}_i)^2 \tag{12}$$

In section 5 we use a leave-one-out cross-validated quadratic probability measure (CVQPM). Here, the parameters in the appreciation score $a_Q(i)$ are computed in the absence of $\mathbf{x}_i$.

It is worthwhile to give some consideration to procedures that can be used for selecting combinations of variables. For example, two features chosen separately may produce less favourable results than two features chosen in combination. With high-dimensional data it is not realistic to perform an exhaustive search of every possible combination of variables. In this case, stepwise methods can be useful. A forward stepwise search sequentially incorporates variables into the discriminant procedure that contribute to the discrimination power of the model. Generally, variables cease to enter the model when little or no change to the performance of the discriminant model is registered. Conversely, a backward stepwise search removes variables from the model until the performance of the model begins to deteriorate. In the presence of high-dimensional data, it is not advisable to use a backward stepwise search, since initially all the variables will be fed to the classifier, which will lead to ill- and poorly-posed situations, not to mention the computational expense and the numerical instabilities which are likely to arise. If desired, a backward selection scheme could be used, following the implementation of a forward, stepwise selection method.

3.2 Feature Transformation

The procedure for calculating a new set of features is called feature transformation. Examples of spectral features that may be informative include the heights, positions or shapes of peaks. Other features commonly used include principal components and Fourier coefficients, while more recently wavelet coefficients[4,15,18–25] have been investigated. These features are obtained by a transformation called the DWT.

The advantage of using features from the wavelet transform, as opposed to principal components, is that the DWT takes into consideration the ordering or incrementation of the variables. This order information is not contained in the principal components. An alternative procedure is Fourier transform (FT) which does take this ordering into consideration, but offers a broader, more global description of a spectrum or signal. The DWT is able to break the spectra into pieces at different scales and analyze the frequency content of each piece. This allows the DWT to convey localized frequency information about a spectrum, and such information can be quite useful for classification purposes.

4 WAVELET TRANSFORMS OF DISCRETE DATA

4.1 Discrete Wavelet Transform

Consider the finite length, discretely sampled spectrum $\mathbf{x} = (x_1, x_2, \ldots, x_{p=2^J})$ of dimensionality $p = 2^J$ for some $J \in \mathcal{Z}^+$. The DWT for such a spectrum can be likened to a series of filtering operations. There are various procedures such as zero padding which can be implemented if $p \neq 2^J$ (see Bruce and Gao[24] and Misiti[25]). The raw spectrum $\mathbf{x}$, which we also call $\mathbf{c}_J$ for ease of notation, passes through a lowpass $\mathbf{L}$ and a highpass $\mathbf{H}$ filter to produce the decimated sequences $\mathbf{c}_{J-1}$ and $\mathbf{d}_{J-1}$, each of dimensionality 2^{J-1}. The scaling coefficients $\mathbf{c}$ are the outputs from the lowpass filter, and the wavelet coefficients $\mathbf{d}$ are the outputs from the highpass filter. The subscript $j \in \{0, 1, \ldots, J\}$ indicates which level the coefficients are from in the DWT, with J initially being the highest level. The general procedure for the DWT continues by passing the scaling coefficients $\mathbf{c}_j$ at level j through a lowpass and a highpass filter to produce the scaling $\mathbf{c}_{j-1}$ and wavelet coefficients $\mathbf{d}_{j-1}$ at the next lower level $j-1$. The scaling and wavelet coefficients at the lowest level j_o in the DWT, as well as the wavelet coefficients at higher levels, comprise the DWT. That is, the DWT contains the coefficients $\mathbf{c}_{j_o}, \mathbf{d}_{j_o}, \mathbf{d}_{j_o+1}, \ldots, \mathbf{d}_{J-1}$. Because of the decimation procedure which forms part of the filtering operations, the number of scaling and wavelet coefficients halve when moving from one level to the next lower level of the DWT, so that the dimensionality of the scaling or wavelet coefficients at some level j is 2^j.

The filtering operations from any level j to $j-1$ can be defined by the matrix operations

$$\mathbf{c}_{j-1} = \mathbf{L}_j\mathbf{c}_j$$
$$\mathbf{d}_{j-1} = \mathbf{H}_j\mathbf{c}_j$$

In summation notation this can be written as shown in Equations (13) and (14)

$$c_{j-1,i} = \sum_{k=0}^{N_f-1} \ell_k c_{j,2i+k} \tag{13}$$

$$d_{j-1,i} = \sum_{k=0}^{N_f-1} h_k c_{j,2i+k} \tag{14}$$

where there are N_f lowpass (ℓ_k) and highpass (h_k) filter coefficients, respectively. In this discussion periodic boundary conditions were assumed.

$$c_{j,k} = c_{j,2^{j+k}}$$
$$d_{j,k} = d_{j,2^{j+k}}$$

Figure 2 indicates how the wavelet coefficients and scaling coefficients are calculated for some discrete spectrum $\mathbf{x} = (x_0, \ldots, x_7)^T = (c_{3,0}, \ldots, c_{3,7})^T = \mathbf{c}_3$ of length $p = 8$. Obviously, in practice the dimensionality of spectra will usually be much greater than $p = 8$. This example is to simply present the underlying principle of the DWT. Initially, all the data $\mathbf{c}_3$, are passed through the low- and highpass filters to give the scaling $\mathbf{c}_2 = (c_{2,0}, \ldots, c_{2,3})^T$ and wavelet $\mathbf{d}_2 = (d_{2,0}, \ldots, d_{2,3})^T$ coefficients at the next lower level. As one progresses down the tree, the number of elements in each of the bands is reduced by half.

If for example $N_f = 2$, then the lowpass filter coefficient matrices would be defined as in Equations (15–17).

$$\mathbf{L}_3 = \begin{matrix} \ell_0 & \ell_1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \ell_1 & \ell_0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & \ell_0 & \ell_1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & \ell_0 & \ell_1 \end{matrix} \tag{15}$$

$$\mathbf{L}_2 = \begin{pmatrix} \ell_0 & \ell_1 & 0 & 0 \\ 0 & 0 & \ell_0 & \ell_1 \end{pmatrix} \tag{16}$$

$$\mathbf{L}_1 = \begin{pmatrix} \ell_0 & \ell_1 \end{pmatrix} \tag{17}$$

Likewise, the highpass filter coefficient matrices would have the same structure as the $\mathbf{L}_3$, $\mathbf{L}_2$ and $\mathbf{L}_1$ matrices, the main difference being ℓ_i would be substituted with h_i.

For future reference, band(j, τ) will indicate the τth band at the jth level of the DWT. The band at the top of the tree is then band(3,0). The bands at the next lower level, are band(2,0) and band(2,1). The scaling coefficients at some level j will be contained in band(j,0), and the wavelet coefficients at the same level will be stored in band(j,1).

Figure 2 Two-band DWT of a spectrum of dimensionality 8.

Figure 3 shows the effect of performing the DWT on an artificially generated spectrum. The spectrum contains 256 points and consists of a sine curve with a period of 2, sampled over $-\pi$ to π, a block pulse, and another sine curve which has a period of 5 over the same interval $-\pi$ to π. For display purposes only, the DWT is shown for the first six levels $j = 8,7,6,5,4,3$. The original spectrum in band(8,0) undergoes a lowpass filtering process to give the scaling coefficients in band(7,0). The original spectrum also undergoes the highpass filtering process to give the wavelet coefficients which lie in band(7,1).

Next, the scaling coefficients in band(7,0) are passed through the lowpass and highpass filters to give the scaling coefficients in band(6,0) and the wavelet coefficients in band(6,1). The same procedure continues with the scaling coefficients from band(6,0) being filtered to give the scaling coefficients in band(5,0) and the wavelet coefficients in band(5,1). This process could continue for $\log_2 256 = 8$ levels, in which case there would be one scaling coefficient and one wavelet coefficient.

As one moves down the tree, the filtered signals in the scaling bands become smoother and smoother. The lowpass filtering process can be likened to a smoothing procedure followed by decimation (i.e. subsampling). The wavelet bands highlight the information which has not been captured by the scaling bands.

The components with the highest frequency are the first to be removed from the scaling coefficients and captured by the wavelet coefficients. Consider for example the scaling coefficients in band(5,0) – the remains of the $\sin(5t)$ are almost undetected in the scaling coefficients, whereas the coefficients of the $\sin(2t)$ curve are more perceptible. The most noticeable feature in the lower scaling levels of the tree is due to the low-frequency event of the block pulse.

4.2 Wavelet Packet Transform

So far we have only considered filtering the scaling coefficients, but it seems perfectly plausible to filter the wavelet coefficients. The wavelet packet transform (WPT)[5] is obtained by filtering both the scaling and wavelet coefficients.

The WPT has a tree-like structure, where each band in the transform produces two new children bands at the next lower level. The tree-like structure occurs because the detailed (or wavelet) coefficients are filtered through a lowpass and a highpass filter to obtain the next lower level of the WPT. This is done in the same way that the smoothed (or scaling coefficients) are filtered. It is convenient if we introduce the notation $\mathbf{x}^{[j]}(\tau)$

Figure 3 Two-band DWT performed on a generated spectrum to level 3.

to represent the wavelet packet coefficients (WPCs) which occur at the jth level in the τth band of the decomposition.

Figure 4 presents the structure of a WPT for some discretely sampled signal $\mathbf{x} = (x_0, x_1, \ldots, x_{2^J-1})^T = \mathbf{x}^{[J]}(0)$. The $(J-1)$ level of the WPT would be obtained as for the DWT, that is the data are passed through a lowpass and a highpass filter so that

$$\mathbf{x}^{[J-1]}(0) = \mathbf{L}_J\, \mathbf{x}^{[J]}(0)$$
$$\mathbf{x}^{[J-1]}(1) = \mathbf{H}_J\, \mathbf{x}^{[J]}(0)$$

For the WPT, the number of bands doubles from one level to the next (lower) level, since each of the bands in the previous level is passed through a lowpass and a highpass filter. At the next level, there will be four bands of WPCs which are obtained by

$$\mathbf{x}^{[J-2]}(0) = \mathbf{L}_{J-1}\,\mathbf{x}^{[J-1]}(0)$$
$$\mathbf{x}^{[J-2]}(1) = \mathbf{H}_{J-1}\,\mathbf{x}^{[J-1]}(0)$$
$$\mathbf{x}^{[J-2]}(2) = \mathbf{L}_{J-1}\,\mathbf{x}^{[J-1]}(1)$$
$$\mathbf{x}^{[J-2]}(3) = \mathbf{H}_{J-1}\,\mathbf{x}^{[J-1]}(1)$$

The same procedure may continue until there is one WPC in each of the bands. In general, $\mathbf{x}^{[j]}(0) = \mathbf{c}_j$ and $\mathbf{x}^{[j]}(1) = \mathbf{d}_j$.

4.3 Local Discriminant Basis Algorithm

The local discriminant basis (LDB) algorithm of Saito and Coifman[15] selects coefficients from the WPT and then uses these coefficients for classification. The selection of the coefficients involves several steps. The first step is to perform the WPT for each object $\mathbf{x}_{i(r)}$ for $i = 1, \ldots, n, \quad r = 1, \ldots, R$. Saito and Coifman[15] then calculate what they refer to as an ''energy map''. This is done for each class $r = 1, \ldots, R$. The energy maps have the same structure as the WPT, hence the same indices are used to locate items within the energy map (or tree). If $\mathbf{e}^{[j]}_{(r)}(\tau)$ denotes the energy coefficients in band(j, τ) of the energy map for class r, then Equation (18) represents the sum of squares of the coefficients that occur in the same position of the wavelet packet tree divided by a normalization constant.

$$\mathbf{e}^{[j]}_{(r)}(\tau) = \frac{\operatorname{diag}\left(\sum_{i=1}^{n_r} \mathbf{x}^{[j]}_{i(r)}(\tau) \quad \mathbf{x}^{[j]}_{i(r)}(\tau)\right)^T}{\text{const}} \tag{18}$$

The energy maps are obtained from the data objects that belong to class r. The notation $\mathbf{x}^{[j]}_{i(r)}(\tau)$ refers to the WPCs in band(j, τ) of the WPT produced from the object vector $\mathbf{x}_{i(r)}$.

Once the energy maps have been constructed for each class, Coifman[15] apply the best basis algorithm[26] to find an *optimal tree*. This involves selecting bands of coefficients which run horizontally across the WPT without overlapping vertically, i.e. no band can lie directly beneath or above another band. In the case of the LDB algorithm, this set of bands should collectively maximize some discriminant criterion $\mho$.

To find the bands of the optimal tree, one starts at the lowest level j_o in the WPT and works up. Initially, the criterion measures for each of the bands of coefficients at level $j_o + 1$ are compared with the criterion measures for the bands of the coefficients in the descendants at level j_o. If the criterion measure of the parent node is superior to that of the descendant nodes then the descendant nodes are deleted. If the descendant nodes produce a superior criterion measure then the descendant nodes are kept and the parent node is deleted. This procedure continues all the way to the top of the tree and the optimal tree consists of the bands that were not deleted in the elimination process.

A symmetric entropy discriminant criterion[10] is used in section 5 to measure the distinctness of the bands, as shown in Equation (19)

$$\begin{aligned}\mho(j, \tau) &= E_{\text{sym}} \quad \mathbf{e}^{[j]}_{(1)}(\tau), \ldots, \mathbf{e}^{[j]}_{(R)}(\tau) \\ &= \sum_{l} \sum_{r:\, r \neq l} E \quad \mathbf{e}^{[j]}_{(l)}(\tau), \mathbf{e}^{[j]}_{(r)}(\tau) \quad + E \quad \mathbf{e}^{[j]}_{(r)}(\tau), \mathbf{e}^{[l]}_{(r)}(\tau)\end{aligned} \tag{19}$$

where $E(\mathbf{w}, \mathbf{g})$ is calculated as shown in Equation (20)

$$E(\mathbf{w}, \mathbf{g}) = \sum_{i=1}^{p} w_i \log \frac{w_i}{g_i} \tag{20}$$

and $p = \text{length}(\mathbf{w}) = \text{length}(\mathbf{g})$. Here, $\mathbf{w}$ and $\mathbf{g}$ are two vectors whose similarity (or dissimilarity) is to be quantified. The entropy measure requires $w_i = g_i = 1$.

Once the optimal tree has been found, it is necessary to choose a subset of the WPCs, since the number of WPCs corresponding to the best basis is still equal to the dimensionality of the original data vector. Saito and Coifman[15] mention that one way of selecting a subset

Figure 4 WPT.

is to choose the WPCs from the optimal tree that have the largest ratio of between-groups variance to within-groups variance, as described in section 3. Alternatively, one could select the WPCs based on another criterion, such as the entropy criterion.

4.4 Adaptive Wavelet Algorithm

There are several "off-the-shelf" wavelets that are defined by their respective filter coefficients. These include, for example, the Daubechies wavelets, coiflets, symlets and the Meyer and Haar wavelets (see for example Daubechies[27]). An initial problem is to decide which set (or family) of filter coefficients will produce the best results for a particular application. In practice, several families of filter coefficients may be trialled, and the family that produces the most desirable results is used. It can be advantageous however, to design your own task-specific filter coefficients rather than using a predefined set. The AWA of Mallet et al.[21] avoids the need to preselect a family of filter coefficients. In Mallet et al.,[21] the filter coefficients are designed with the aim of assigning objects to their respective classes with the greatest degree of accuracy.

4.4.1 m-Band Discrete Wavelet Transform

The AWA is presently based on the DWT rather than the WPT, but uses the more general m-band DWT ($m \geq 2, \quad m \in \mathcal{Z}^+$) where there is one lowpass filter, and $m-1$ highpass filters. We prefer to have the dimensionality $p = m^{(J-j_o)}$ and set $J = \lceil \log p / \log m \rceil$.

A three-band DWT for the spectrum $\mathbf{x} = (x_0, x_1, \ldots, x_8)$ is shown in Figure 5. There is one lowpass filter and two highpass filters, producing one set of scaling (or smoothed) coefficients and two sets of wavelet (or detailed) coefficients, respectively. As before, to traverse from one level to the next, only the scaling coefficients are filtered and the number of coefficients in each band is reduced by a factor of $m = 3$.

Figure 5 A three-band DWT.

The filtering operations for the general m-band DWT from some level j to level $j-1$ can be described by the matrix operations

$$\mathbf{c}_{j-1} = \mathbf{L}_j \mathbf{c}_j$$
$$\mathbf{d}_{j-1}^{(z)} = \mathbf{H}_j^{(z)} \mathbf{c}_j \qquad z = 1, \ldots, m-1$$

In summation notation one has Equations (21) and (22)

$$c_{j-1,i} = \sum_{k=0}^{N_f-1} \ell_k c_{j,mi+k} \tag{21}$$

$$d_{j-1,i}^{(z)} = \sum_{k=0}^{N_f-1} h_k^{(z)} c_{j,mi+k} \qquad z = 1, \ldots, m-1 \tag{22}$$

where it is assumed

$$c_{j,k} = c_{j,m^j+k}$$
$$d_{j,k}^{(z)} = d_{j,m^j+k}^{(z)}$$

Following the same notation as introduced earlier, band(j, τ) will be referred to as the τth band at the jth level of the DWT. The band at the top of the tree in Figure 5 is band(2,0). At the next level the bands from left to right are referred to as band(1,0), band(1,1) and band(1,2). Similarly, the bands in the last level of the DWT are band(0,0), band(0,1) and band(0,2).

The AWA provides one way of generating suitable filter coefficients for performing the m-band DWT ($m \geq 2$). This is done by placing constraints on the filter coefficients and then searching for suitable filter coefficients that satisfy these constraints. More details on the m-band DWT are available in the literature.[5,28,29]

4.4.2 Filter Coefficient Conditions

There are restrictions imposed on the filter coefficients so that a two-band (or higher) DWT or WPT can be performed. The adaptive wavelet should also adhere to these conditions. Let $\boldsymbol{A}$ denote the $m \times N_f$ matrix, with the first row containing the lowpass filter coefficients and the remaining $m-1$ rows containing the sets of highpass filter coefficients, as shown in Equation (23).

$$\boldsymbol{A} = \begin{matrix} \ell_0 & \ell_1 & \ldots & \ell_{N_f-1} \\ h_0^{(1)} & h_1^{(1)} & \ldots & h_{N_f-1}^{(1)} \\ \vdots & \vdots & & \vdots \\ h_0^{(m-1)} & h_1^{(m-1)} & \ldots & h_{N_f-1}^{(m-1)} \end{matrix} \tag{23}$$

$\boldsymbol{A}$ can be partitioned into $q+1$, $m \times m$ sub-matrices as follows: $\boldsymbol{A} = (\boldsymbol{A}_0 \, \boldsymbol{A}_1 \, \ldots \, \boldsymbol{A}_q)$. The conditions imposed on

the filter coefficients so that an orthogonal wavelet basis exists can be summarized as follows.[30,31]

1. Orthogonality: $\sum_k \boldsymbol{A}_k \boldsymbol{A}_{k+i}^T = \delta_{0i}\boldsymbol{I}$, where $\delta_{0i} = 1$ if $i = 0$, and zero otherwise, and $\boldsymbol{I}$ is the identity matrix.
2. Regularity: $\sum_k \ell_k = \sqrt{m}$.
3. The Lawton matrix condition, $M_{ij} = \sum_k \ell_k \ell_{k+j-mi}$, must have 1 as a simple eigenvalue.

(More sophisticated wavelet and scaling functions will satisfy additional conditions.)

The AWA attempts to find the elements of $\boldsymbol{A}$ which optimize the discriminant problem at hand. Instead of optimizing over each filter coefficient in $\boldsymbol{A}$, the AWA makes use of the factorized form[21,30,31] of a wavelet matrix and the conditions placed therein to reduce the number of parameters to be optimized. It can be shown[31] that $\boldsymbol{A}$ can be constructed from some set of normalized vectors denoted by $\boldsymbol{u}_1, \ldots, \boldsymbol{u}_q$ and $\boldsymbol{v}$, where the total number of parameters to be optimized is $N_f - 1$.

Table 1 Description of the spectral data sets used for classification

Data		Class 1	Class 2	Class 3	Class 4	Class 5	Total
Seagrass	Train	55	55	55	–	–	165
	Test	34	34	34	–	–	102
Mineral	Train	20	20	20	20	20	100
	Test	20	20	20	20	20	100
p-Xylene	Train	25	25	25	–	–	75
	Test	25	25	25	–	–	75
Butanol	Train	21	27	–	–	–	48
	Test	21	26	–	–	–	47

5 APPLICATIONS

5.1 Data Sets

Four spectral data sets were used to investigate the various classification procedures. Each data set initially contained 512 variables (i.e. $p = 512$). The data sets are referred to as the seagrass, mineral, *p*-xylene and butanol data sets. The number of training and testing spectra in the group categories is listed in Table 1 for each set of data. Sample spectra from each of these data sets are presented in Figures 6–9.

5.2 Methodology

There are many different classification and feature extraction strategies that can be applied to spectral data.

Figure 6 Five sample spectra from the seagrass data.

Figure 7 Five sample spectra from the mineral data.

Figure 8 Five sample spectra from the *p*-xylene data.

Figure 9 Five sample spectra from the butanol data.

Collectively, the term strategy refers to the particular classifier utilized, such as RDA, or a feature extraction technique. A strategy may even refer to the combination of feature extraction methods with a particular classifier. The classification strategies are described in the following sections.

5.2.1 Stepwise Bayesian Linear and Quadratic Discriminant Analysis

A stepwise feature selection method is used to select variables from the original data set. These selected variables then undergo BLDA and BQDA. If the stepwise feature selection procedure is used in combination with BLDA, the classification strategy is referred to as SBLDA (stepwise Bayesian linear discriminant analysis). Likewise, if BQDA is the classifier then the procedure is called SBQDA (stepwise Bayesian quadratic discriminant analysis).

The stepwise procedure considered here starts with an empty subset, and at each step adds the variable (or wavelength) that produces the largest increase in the CVQPM. The procedure ceases to enter variables into the model when one of the following stopping criteria is reached.

- The change in the correct classification rate (CCR) is less than $1/n$, where n is the number of samples in the data set. That is, from one iteration to the next, the inclusion of another variable does not improve the CCR by more than $1/n$.
- The CCR reaches 100%.

The results of the stepwise strategies for both SBLDA and SBQDA are summarized in Table 2. SBLDA produced a higher test CCR for the seagrass and *p*-xylene data, while SBQDA produced a higher test CCR for the mineral and butanol data. The butanol data set posed the greatest challenge for the stepwise procedures.

Table 2 Percentage of correctly classified objects for SBLDA and SBQDA

Data		SBLDA	SBQDA

	Test	**100**	97.06
Mineral	Train	100	100
	Test	88	**93**
p-Xylene	Train	100	100
	Test	**87.33**	78.67
Butanol	Train	87.50	89.58
	Test	72.39	**76.60**

5.2.2 Flexible and Penalized Discriminant Analysis

The regression method used for FDA was bruto. Bruto is an additive regression model which computes the terms in the model using smoothing splines. The bruto procedures also accommodate a feature selection routine. The regression method used for PDA was ridge regression. Both FDA and PDA were applied to the original data sets without prior feature selection. FDA, when used in conjunction with bruto, can be seen as a monothetic method since, while it is initially supplied with all of the variables, it eventually selects a much smaller subset. PDA (and RDA) on the other hand can be seen as polythetic methods, since all of the variables are entered into the final model. The classification results for FDA and PDA are displayed in Table 3. For all data sets except for the mineral data, FDA outperformed PDA in terms of the misclassification rate of the test data. Again the

Table 3 Percentage of correctly classified objects for FDA and PDA

Data		FDA	PDA

	Test	**86.67**	81.33
Butanol	Train	75	43.68
	Test	**70.21**	43.75

Table 4 Percentage of correctly classified objects for RDA and the regularization parameters

Data		RDA	(λ, γ)
Seagrass	Train	99.39	(1.00, 0.25)
	Test	99.02	
Mineral	Train	100	(1.00, 0.25)
	Test	95	
p-Xylene	Train	100	(0.25, 0.25)
	Test	100	
Butanol	Train	87.50	(1.00, 0.25)
	Test	87.23	

butanol data set was the more challenging data set to classify, especially for PDA.

5.2.3 *Regularized Discriminant Analysis*

RDA was applied to each data set with 25 different (λ, γ) combinations. The combinations resulted from each pairwise combination of the settings 0.00, 0.25, 0.50, 0.75 and 1.00. Table 4 presents the training and test classification rates for each data set as well as the corresponding (λ, γ) grid settings that were used to produce the respective classification rates.

Again, reasonable classification rates were experienced for the seagrass and mineral data. Of interest however is the fact that all of the spectra from the training and testing *p*-xylene data were correctly classified using RDA. From previous applications, the *p*-xylene data (along with the butanol data) posed a challenge for many of the classification strategies.

The $(\lambda, \gamma) = (1.00, 0.25)$ setting was found to be optimal for the seagrass, mineral and butanol data sets. This indicates that for these data sets a pooled covariance matrix is preferred to one that is not pooled. The combination $(\lambda, \gamma) = (0.25, 0.25)$ was used for the *p*-xylene data set, as it weights the individual class covariance matrices more heavily than the pooled class covariance matrix.

5.2.4 *Banded Bayesian Linear and Quadratic Discriminant Analysis*

Perhaps the simplest strategy to incorporate wavelet-based methods with classification strategies is to choose a family of filter coefficients, perform the DWT, and then supply all the coefficients from some band(j, τ) to a classifier. The term ''coefficients'' is used loosely to refer to either wavelet or scaling coefficients. We used the $m = 2$ band DWT with $N_f = 16$ filter coefficients from the Daubechies family. The classifiers used were BLDA and BQDA. Since these are low-dimensional methods, the number of coefficients in band(j, τ) should be small when compared with the sample size, so that an ill- or poorly-posed situation is avoided. The banded approach is a very simple procedure for feature selection of the wavelet coefficients. Previously, Bos and Vrielink[18] used a similar approach, except that the bands of coefficients were supplied to neural networks. The coefficients from band(3,0), band(3,1), band(4,0) and band(4,1) were supplied to the classifiers.

The terms BBLDA (banded Bayesian linear discriminant analysis) and BBQDA (banded Bayesian quadratic discriminant analysis) are adapted if the bands of coefficients are supplied to BLDA or BQDA, respectively. The classification results for BBLDA and BBQDA are summarized in Tables 5 and 6 respectively. The wavelet bands tended to dominate for BBLDA for the mineral, *p*-xylene and butanol data sets. For BBQDA, numerical

Table 5 Classification results for BBLDA

Data		$\mathbf{X}^{[3]}(0)$	$\mathbf{X}^{[3]}(1)$	$\mathbf{X}^{[4]}(0)$	$\mathbf{X}^{[4]}(1)$
Seagrass	Train	98.79	99.39	100	100
	Test	**100**	98.04	**100**	99.02
Mineral	Train	97	95	97	98
	Test	87	90	94	**98**
p-Xylene	Train	62.67	68.00	81.33	80.00
	Test	50.67	58.67	56.00	**61.33**

	Test	82.98	82.98	76.60	**87.23**

The numbers in the square brackets are the level of the transform.

Table 6 Classification results for BBQDA

Data		$\mathbf{X}^{[3]}(0)$	$\mathbf{X}^{[3]}(1)$	$\mathbf{X}^{[4]}(0)$	$\mathbf{X}^{[4]}(1)$
Seagrass	Train	100	100	100	100
	Test	**100**	99.02	**100**	**100**
Mineral	Train	100	100	–	–
	Test	93	**96**	–	–
p-Xylene	Train	88	86.67	100	100
	Test	66.67	72.00	**81.33**	76.00
Butanol	Train	89.58	87.50	100	100
	Test	**74.47**	72.34	63.83	57.45

The numbers in the square brackets are the level of the transform.

instabilities arose for the mineral data when 16 coefficients were supplied to the classifier. This can be attributed to the fact that, for BQDA, the class sample size should be large compared with the dimensionality. For the mineral data there are 20 objects per class, which is only marginally larger than the number of coefficients (16), hence it was not possible to produce accurate results for this setting.

5.2.5 *Stepwise Feature Extraction from the Discrete Wavelet Transform*

A more sophisticated procedure for incorporating wavelet-based methodologies with classification strategies is to use a stepwise selection procedure to select the coefficients which are to be supplied to the respective classifier. As for the banded procedures described in the previous section, the two-band DWT is performed to level 3 using a Daubechies wavelet defined by 16 filter coefficients. The bands shaded in grey in Figure 10 indicate the total set of bands from which wavelet or scaling coefficients may be selected from the stepwise procedure. The same stepwise routine used for SBLDA and SBQDA is also applied here to the coefficients $\mathbf{c}_3, \mathbf{d}_3, \mathbf{d}_4, \ldots, \mathbf{d}_8$. If the coefficients are supplied to BLDA we refer to this classification procedure as SWBLDA, and when the classifier is BQDA the procedure is referred to as SWBQDA.

Also indicated in Figure 10 are the coefficients selected by SWBLDA (asterisk) and SWBQDA (circle). It should be noted that for the challenging *p*-xylene and butanol data sets there are more coefficients selected from higher levels in the DWT, indicating that the classifiers are discriminating using information relating to high-frequency events. For the seagrass and mineral data, however, it should be noted that the classifiers select coefficients from the lower levels, and in fact some scaling coefficients are selected, indicating that information relating to the basic shape of the mineral and seagrass data has been utilized.

The classification results for SWBLDA and SWBQDA are shown in Table 7. The *p*-xylene data set is the only data set which gives a higher test CCR using SWBQDA as opposed to SWBLDA. Whilst SWBLDA does outperform SWBQDA for three of the four data sets in terms of the test misclassification rate, SWBLDA is often outperformed by other classification strategies. SWBLDA does however compare favorably with other classification strategies when applied to the butanol data.

5.2.6 *Local Discriminant Basis*

LDB adds even greater sophistication than the stepwise and banded procedures for combining wavelet features and classification methods. In this section the WPT (with $m = 2$) was calculated to level 3 using the Daubechies

Figure 10 Coefficients selected from the DWT by stepwise wavelet feature extraction using Bayesian linear discriminant analysis (SWBLDA) (asterisks) and stepwise wavelet feature extraction using Bayesian quadratic discriminant analysis (SWBQDA) (circles).

Table 7 Percentage of correctly classified objects for SWBLDA and SWBQDA

Data		SWBLDA	SWBQDA
Seagrass	Train	99.39	100
	Test	**98.04**	97.06
Mineral	Train	100	100
	Test	**93**	90
p-Xylene	Train	98.67	97.33
	Test	81.33	**82.67**
Butanol	Train	85.42	91.67
	Test	**85.11**	74.47

filter coefficients with $N_f = 16$. Once the wavelet packet decomposition had been formed, the best basis (optimal tree) was determined from the energy maps. The criterion used to form the best basis was the symmetric entropy criterion (Equation 19). Figure 11 marks the best basis selected by the LDB algorithm for each of the sets of data. For the *p*-xylene data, the selected best basis was the original data.

Once the best basis had been found, a subset of WPCs was selected from the best basis. It was decided to select the 16 WPCs based on the same discriminant measure which produced the best basis, i.e. symmetric entropy.

The asterisks in Figure 11 show the positions of the 16 WPCs which were selected from the best basis and supplied to the classifier BLDA. The WPCs are quite clustered, which is a likely consequence of selecting the coefficients by a univariate strategy, that is without consideration being given to previously selected features. There is also a tendency for the WPCs to be largely selected from band(4,0) and band(4,1) of the WPT. These bands contain the same coefficients as those in band(4,0) and band(4,1) from the DWT. It should be noted, however, that in Figure 10 there is only one coefficient selected from either of these bands (see mineral data). The conflict in feature selection is a likely consequence of using different selection strategies for selecting features.

The sixteen WPCs with the largest symmetric entropy measures were supplied to the BLDA classifier in a top-down approach using the first $1, 2, \ldots, 16$ coefficients for classification. That is, initially a single WPC (with the largest discriminant measure) was supplied to the classifier. Then, the two WPCs with the largest discriminant measures were supplied to the classifier. This procedure continued until all 16 coefficients had formed part of the BLDA model.

Table 8 gives the classification rates for the training and testing data for each of the discriminant data sets where the first $1, \ldots, 16$ WPCs were selected from the best basis, and supplied to BLDA. The numbers in bold type had the largest (test) CCR and the fewest terms in the discriminant model. This application of the LDB approach closely followed that outlined by Saito and

Figure 11 Selected wavelet coefficients (asterisks) from the best bases.

16	100.00	100.00	99	93	92.00	73.33	87.50	76.60

Coifman,[15] the main difference being that BLDA was used, as opposed to FLDA.

5.2.7 *Adaptive Wavelet Algorithm*

Previous feature extraction methods involving the DWT were performed using filter coefficients from the Daubechies family. Many filter coefficients could have been chosen, but the Daubechies filter coefficients were chosen as they tend to be popular. There is no reason, however, that another set of coefficients could not have been chosen. Of course, the problem lies in deciding whether or not better results might be obtained using another set or family of filter coefficients. In this section, task-specific filter coefficients are designed using the AWA described in section 4.3. The underlying principle of the AWA is to avoid deciding which set of filter coefficients to use, and instead to design the filter coefficients to suit the task in hand, which in this case is discriminant analysis.

The AWA is applied using several settings of the m, q and j_o parameters, where j_o is the lowest level of the DWT and $N_f = m(q+1)$. The particular (m, q, j_o) triplets used were (4,3,2), (4,2,2), (8,1,1), (2,5,3), (2,5,4), (2,7,3), and (2,7,4). These settings were chosen because (1) they provide suitable ratios of the dimensionality of the wavelet bands to the sample size and, (2) the number of filter coefficients is of reasonable size. We considered $N_f = 12$ and $N_f = 16$. Mallet et al.[21] describe some heuristics for choosing these parameters.

The discriminant criterion function implemented by the AWA is the CVQPM criterion function. A form of banded selection was performed, whereby the CVQPM was calculated from a band of coefficients. The same coefficients were later supplied to the classifier. The value τ was chosen as the band which gave the highest CVQPM value at initialization for a particular (m, q, j_o) triplet. For more details on this banded selection process see Mallet et al.[21]

Table 9 Percentage of correctly classified objects for AWA

	m	q	j_o	N_f	N_{coef}	τ	Train	Test
Seagrass	4	3	2	16	8	1	100	100
Mineral	2	7	4	16	16	1	99	99
p-Xylene	2	5	4	12	16	1	94.67	86.67
Butanol	2	5	3	12	8	1	93.75	87.23

The settings which produced the highest test CCR are displayed in Table 9 for each of the data sets. The AWA performed consistently well for each data set. It is interesting to note that for three of the four data sets the more common $m = 2$ band DWT was used.

6 SUMMARY OF RESULTS

This section summarizes the results of the various classification procedures which were accumulated in section 5. Figure 12 displays the CCRs for each of the classification strategies. Only the CCRs for the testing data are displayed. To enable easier interpretation of Figure 12, crosses have been used to indicate the results of the high-dimensional methods, circles have been used to indicate the low-dimensional classification performed on the original data, and the asterisks indicate the low-dimensional classification methods based on the coefficients from the DWT. To

further enhance interpretation of Figure 12, the line types also change with the marker indicators. Table 10 shows the actual CCRs for the training and testing data sets.

The most salient issues that have arisen from the comparative analysis are as follows.

- RDA tends to outperform the other high-dimensional classifier PDA, with the exception being for the mineral data where PDA outperforms RDA.
- If RDA is compared with the low-dimensional methods which entail some form of feature extraction (or selection), then it can clearly be seen that RDA also consistently produces high classification results across each of the sets of data. For the mineral data, however, RDA is outperformed by three of the wavelet-based approaches (and PDA).
- For the classification methods SBLDA, SBQDA and FDA there does not appear to be any one approach that consistently performs well.

- The AWA consistently produces high test classification rates and compares favourably against the high-dimensional classifiers and the classification strategies involving a low-dimensional classifier.
- There appears to be some variability in the performance of the wavelet-based techniques in that, with the exception of the AWA, no wavelet method performs consistently well or consistently outperforms the other strategies.

7 CONCLUSION

This paper has presented several different strategies that can be used for classifying spectral and similar forms of data. We considered two main approaches – using a high-dimensional classifier for all of the original data, and using a low-dimensional classifier on selected features. The features considered were the original variables, and coefficients from the DWT were also explored. The objective of this paper was to compare the performances of each of these strategies. Based on the CCR it was noted that the high-dimensional classifier RDA performed consistently well. It was difficult to observe if any low-dimensional classifier consistently produced outstanding performances. This subjectivity arose due to the different feature selection strategies which were implemented in conjunction with the classifiers BLDA, BQDA and FDA. However, the AWA did consistently produce high CCRs and compared favourably with RDA. This demonstrates that it can be advantageous to design your own task-specific filter coefficients.

Throughout this paper, much attention has been focused on the CCR for comparing techniques. It should be mentioned that there are many other attributes which should be addressed when comparing techniques. Computational complexity is one item which should be considered. Although a comprehensive analysis of computational complexities was not undertaken, in our experience RDA and the AWA tend to be much more computationally expensive than the remaining methods. This is obviously due to the optimization routines which form part of these techniques.

Another attribute is the qualitative information and interpretability that can be obtained from the models. For example, whether the model can discover which variables are more important, or whether the model has graphical capabilities for exploring group separation, for instance. The Bayesian classification methods BLDA, BQDA and RDA are difficult to interpret qualitatively. However, when BLDA and BQDA are combined with stepwise methods then some insight into discriminatory regions of the data is obtained by noting which variables have been selected. This is the case whether selection is from the original data or from wavelet coefficients. The wavelet procedures which involve a banded selection of coefficients do not allow for easy interpretation, although if FLDA was applied to these features then one could examine the size of the discriminant coefficients to indicate which coefficients are more important. A useful feature of both PDA and FDA is that these methods can generate discriminant plots.

To provide more detailed comparisons, further work on more data sets, including simulated data, needs to be performed. Here we have simply introduced some traditional and modern methods for classifying spectral data and quantitatively examined their performances using the CCR, to help provide the reader with more insight into these techniques.

ABBREVIATIONS AND ACRONYMS

AWA	Adaptive Wavelet Algorithm
BBLDA	Banded Bayesian Linear Discriminant Analysis
BBQDA	Banded Bayesian Quadratic Discriminant Analysis
BLDA	Bayesian Linear Discriminant Analysis
BQDA	Bayesian Quadratic Discriminant Analysis
CCR	Correct Classification Rate
CVQPM	Cross-validated Quadratic Probability Measure
DWT	Discrete Wavelet Transform
FDA	Flexible Discriminant Analysis
FLDA	Fisher's Linear Discriminant Analysis
FT	Fourier Transform
LDB	Local Discriminant Basis
MARS	Multivariate Adaptive Regression Splines
NIR	Near-infrared
PDA	Penalized Discriminant Analysis
PLSR	Penalized Least Squares Regression
QPM	Quadratic Probability Measure
RDA	Regularized Discriminant Analysis
SBLDA	Stepwise Bayesian Linear Discriminant Analysis
SBQDA	Stepwise Bayesian Quadratic Discriminant Analysis
SWBLDA	Stepwise Wavelet Feature Extraction Using Bayesian Linear Discriminant Analysis
SWBQDA	Stepwise Wavelet Feature Extraction Using Bayesian Quadratic Discriminant Analysis

WPC	Wavelet Packet Coefficient
WPT	Wavelet Packet Transform

Infrared (IR) spectroscopic analysis is one of the most important means of structure determination of organic compounds because it can provide much information about the molecular structures of compounds. Innumerable IR spectra have been measured since the Coblentz collection was published in 1905 and many catalogs (printed collections and, further, computer IR databases) have been developed. These experimental data were very useful in the structure elucidation process, and many studies have been conducted on the relationships between various organic functional groups and their absorption bands. Usually, chemists make structural analyses using two methods. One method is to search a library of standard spectra and to find the closest match to the unknown spectrum [library search (LS) Method]. The other method is to find characteristic spectral features (connected with some parts of a chemical molecule), which is based on the empirical examination of a large number of spectra of known compounds. The conventional process of structure elucidation can be time-consuming, especially in the case of complex, multifunctional compounds. Computers offer the promise of enhanced human productivity in this field. A number of systems for searching a collection of spectral data in order to find reference spectra, identical with or similar to a spectrum of an unknown compound, have been developed. The systems may also retrieve other information, such as molecular formulas, chemical names, Chemical Abstracts Service (CAS) registry numbers, molecular fragments or complete structures of compounds. Most of the search systems are designed for a single type of spectra (e.g. IR spectra), but there are also some multimethod systems that apply various spectral techniques [IR, nuclear magnetic resonance (NMR), mass spectrometry (MS), Raman or ultraviolet/visible (UV/VIS)] to improve the results of a structure recognition process. The weakness of the LS approach is related to the necessity for a powerful computing system and a large database. Also, even a large database may not contain identical or highly similar reference spectra with respect to the sample spectrum. Thus the LS method can solve the problem of structure identification when the database contains a spectrum identical with (or highly similar to) the sample spectrum. Otherwise, to elucidate the structure of an unknown compound, it is necessary to use computer methods that permit the recognition of structural fragments present in the molecule of the analyzed substance. These programs use correlation tables (a list of structural fragments and their spectral characteristic parameters) that can form a knowledge database or be an integral part of the program. Usually, these parameters are taken from the literature, but they can also be generated from a computer library of IR spectra by computer-simulated neural networks, application of a statistical algorithm or other methods. There are systems for structure recognition which test a large number of spectral and structural features in order to calculate decision functions between the classes of compounds. When applied to a spectrum of an unknown structure, these functions indicate the presence or absence of the respective molecular fragments. Methods of this type include various cluster analyses, pattern recognition methods and computer-simulated neural networks.

The first collections of IR spectra (printed and computer IR databases) were often of poor quality, owing to the low technological level of the spectrometers used. Contemporary IR databases contain spectra of a considerably higher quality owing to the advent of high-resolution spectrometers and proper sample preparation (according to the standards required). Apart from large spectral

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

databases (SDBs) containing data on different chemical compounds, a large number of collections dedicated to specialized groups of compounds are offered. Recently, a new type of printed spectral catalogue has appeared on the market: the traditional form of a book is supplemented by a diskette containing peak tables in a digital format, allowing the reader to search for unknowns. As far as the computer databases are concerned, many efforts are aimed at the unification of spectral and chemical structure codes, which will assist an easy exchange of information between various scientific centers. The International Union of Pure and Applied Chemistry (IUPAC) has additionally published a very positive opinion about the Joint Committee on Atomic and Molecular Physical Data (JCAMP) format which makes it very probable that this format will be broadly used in future.

All the above-mentioned issues are discussed in this article, with detailed focus on (1) history of printed and computer IR collections, (2) more important IR databases, (3) standards in IR databases, (4) structure of IR databases, (5) monomethod identification of chemical compounds and (6) application of multimethod SDBs to structure elucidation.

1 INTRODUCTION

Recognition of a chemical structure, realized nowadays by spectroscopic methods, is very important in many research fields, e.g. in chemical analysis, organic synthesis (identification of main reaction products, determination of by-product chemical structures), pharmacology (recognition of the structure of pharmacologically active compounds, investigation of drugs and pesticides metabolism) and others. Irrespective of the applied spectral methods, the basic step in structure elucidation is the interpretation of the spectrum. This process is intellectually difficult, demands a professional education, experience and very often also intuition. For the interpretation of spectra, the chemist uses mainly semiempirical methods which are based on large amounts of previously accumulated reference data (spectra libraries, tables of spectrum–structure correlations). As searching through large collections of data and selecting and applying various empirical rules by conventional means is generally very time-consuming and often boring, many approaches to the computer-aided (semiempirical) interpretation of spectral data have been proposed. Three basically different techniques may be distinguished.

In the most commonly used method, called the LS method, the computer scans a reference spectra collection, comparing the spectrum of an unknown compound with each spectrum of a reference set. The structures of those reference compounds having spectral data most similar to the unknown are considered to be similar to the unknown (analyzed) structure. In the second method, the computer tests (learning phase) a large number of spectral and structural features in order to calculate a decision function between the classes of compounds. When applied to a spectrum of an unknown structure, this function indicates the presence or absence of the respective structural features (substructures, molecular fragments). Methods of this type include various cluster-analysis and pattern-recognition methods. Computer-simulated neural networks can also be acknowledged as a method of this type, although the classification function in the networks is unknown.

The third method is usually employed when the LS fails, i.e. there is a lack of spectra similar to the analyzed spectrum in the spectral library. In this method, spectrum–structure correlations generalized and condensed into a set of interpretation rules are applied to the interpretation of an unknown compound spectrum in order to predict whether the respective substructures are present or absent in the unknown molecule.

The above remarks refer to all kinds of spectra, especially to IR spectrometry. Computer IR SDBs were created before other computer SDBs. The experience gathered during the development of IR databases helped in creating SDBs for other spectral techniques. IR spectrometry was earlier the basic method for chemical structure identification, but later it became only a supporting method for NMR and MS. Nevertheless, most data banks contain IR spectral libraries.

2 HISTORY: MORE IMPORTANT INFRARED DATABASES

2.1 Printed Collections of Infrared Spectra

Before computer IR databases were developed, collections of IR spectra of pure chemical substances had been created in the form of printed catalogs. The first collection of IR spectra was published by Abney and Festing in 1881.[1] This collection contained only 48 spectra. Then, in 1905–1908, Coblentz[2] published his collection of IR spectra containing 135 organic compounds. The development of a quantum theory, wave mechanics and also the possibility of measuring substances at various temperatures and pressures and in different states of concentration indicated the great importance of IR spectroscopy in the investigation of molecular structures. Consequently, the number of IR spectra registered by different laboratories increased dramatically,[3–9] so that various catalogs soon contained even several thousands of spectra. Until the early 1950s, IR collections were printed as books, unfixed sheets (card indexes), slides, microfiches

or microfilms. As the collections of IR spectra increased in content, searching for information became more and more laborious and arduous. Later, a noticeable improvement was obtained by application of cards perforated for spectra presentation and sorting machines to review so-prepared card indexes. The first collections of this kind were elaborated by the American Wyandotte Chemical Corporation in cooperation with the American Society for Testing and Materials (ASTM),[10,11] and the catalog created (comprising 150 000 IR absorption spectra) was constructed using standard Hollerith cards. Various spectra encoded on the cards contained information about band locations, chemical classification of the compound, its chemical formula and a classification number in the original (source) catalog. One year later, the Institute of Applied Spectroscopy in Dortmund and the Institute of Molecular Spectroscopy in London created and disseminated a collection of IR spectra known as the Documentation of Molecular Spectroscopy (DMS) catalog.[3] The system of checking DMS cards was to give the answer to the question, ''Is a spectrum of an unknown compound present in the card index or not?'', and was based on the possibility of defining some classification features, i.e. spectral parameters (the location and intensity of absorption bands at specified intervals), structural parameters (the presence of characteristic structural fragments, e.g. ring systems, substituents, functional groups) and general parameters (e.g. qualitative composition, molecular weight, melting point, boiling point). The classification features were perforated on the card borders (margins) of each collection element (for each chemical compound). As the system was based on punched cards, the searching process could be speeded up by application of electromechanical shakers. The DMS system had a symptomatic feature which was later copied in computer searching systems, namely that it was possible to join different parameters in a logical conjunction within one operation of card-index searching, i.e. to input into a searching matrix of a shaker a set of holes, corresponding to some selected features, to obtain transparency through the cards (i.e. the holes fit together). An example task is to search for ''all cards containing an absorption band located in the 1800–1700 cm^{-1} range, iodide atom and molecular weight below 420''. The system also allowed negative searching, i.e. taking into consideration the lack of a given feature.

The automation of searching through a card index considerably improved the use of catalogs. A user could obtain a reduced set of spectra according to declared earlier parameters, and subsequently look through the remaining spectra manually. In spite of the inconveniences of searching through a large set of spectra, printed catalogs are still acknowledged by chemists, and today handbooks containing IR spectra of chemical substances are still published. For example, books containing IR spectra are as follows: *Raman/IR Atlas of Organic Compounds*[12] (~1000 IR spectra), *The Aldrich Library of IR Spectra*[13] (~12 000 IR spectra), *The Aldrich Library of FTIR (Fourier transform infrared) Spectra*[14] (~18 000 IR spectra), *The Aldrich Library of FTIR Spectra: Vapor Phase*[15] (~6550 IR spectra), *The Aldrich Library of FTIR/Raman Spectra*[16] (~14 000 IR spectra), *Coblentz Society Reference Spectra Collection*[17] (Volume I, 860 IR spectra); some contain only specified types of compounds, e.g. *Coblentz Society Reference Spectra Collection*,[17] Volume II, 282 IR spectra of halogenated hydrocarbons; Volume III, 284 IR spectra of plasticizers and other additives, *Atlas of Polymer and Plastics Analysis*[18] (~6700 IR spectra), *Handbook of Fourier Transform Raman and IR Spectra of Polymers*[19] (500 IR spectra) and *An IR Spectroscopy Atlas for the Coatings Industry*[20] (740 IR spectra).

Some IR collections are published in the form of a WebBook (http://webbook.nist.gov/chemistry), e.g. National Institute of Standards and Technology (NIST) Chemistry WebBook (5000 gas-phase IR spectra). Constantly updated information about books on IR spectra is available on an Internet website, e.g. http://wally.rit.edu/pubs/guides/spectra.html.

2.2 Computer Databases of Infrared Spectra

Developments in hardware technology afforded further progress in the field of SDB creation and the elaboration of algorithms used for searching and interpretation of stored data. The first databases containing IR spectra were coded on magnetic tapes or disks. The type of stored information was changing. It was possible to store not only data about absorption band parameters of the spectrum (see Table 1), but also to record the whole spectrum in a discrete form, which permitted the exact reproduction of a spectral curve (see Table 2). Some more important computer IR databases, developed recently, are presented in Table 3. From the data in these tables, it can easily be concluded that some scientific centers elaborated not only one, but several computer IR databases. The reasons why various IR databases were developed in the same research center were, among others, the application of different sources of information to develop a spectral collection (e.g. SPECTRUM-I was created on the basis of a DMS card index, whereas SPECTRUM-II is based on the Sadtler catalog, Table 1), the use of various algorithms for spectral coding (e.g. ZAPAH and KISIK in Table 1, and three of the Sadtler databases cited in Table 2) and also the separation of certain spectra collections (e.g. a set of polymers in the POLYMER database, see Table 2).

Nowadays, there are two trends of computer database development, i.e. creating larger and larger collections

Table 1 List of some important computer IR databases containing spectra stored as selected parameters of absorption bands

containing spectra of various substances or specialized collections of chemical compounds of a specified type or purpose (polymers and copolymers, plant protection remedies, medicaments, etc.). The application of computer software enables one to generate from a large database some specialized collections, even for individual users (by network mechanisms). This solution was adapted to a database disseminated by Hoechst AG[41] to a network encompassing 20 different laboratories, using FTIR spectrometers from Bruker, Perkin-Elmer, Nicolet and Digilab. The users of this network had access to the central data bank containing selected fragments of Sadtler, Bruker and Hummel collections (6300 standard Sadtler spectra, 9300 Sadtler spectra in the vapor phase, 3200 spectra of Bruker–Merck firm and 2900 spectra from the Hummel–Scholl atlas).

Additionally, access to a small local Hoechst database was included (550 standard spectra, 500 spectra of substances supplemental for polymers, and 300 spectra in the vapor phase). The libraries of the central data bank were accessible only in a read-only procedure, whereas the resources of the second database were continually supplemented (about 25 spectra every week) by analytical laboratories connected to the network (Analytical Lab, Frankfurt; R&D Pigments, Frankfurt; Analytical Lab Kalle, Wiesbaden; Analytical Lab Hoechst, Gersthofen; and others), which produced high-quality spectra.

The analysis of the organization methods of IR databases permits their evaluation. For example, taking into consideration the ASTM catalog created over 30 years (1950–1980), containing at the time about 90 000 standards,[9] it can be stated that limitations imposed on the database at the time of its development (on perforated cards, with application of Hollerith cards with 80 columns) allowed archiving of only some selected bands (coded in micrometers), as opposed to collections containing full discrete spectra, which are nowadays coded in wavenumbers. An additional artifact of the ASTM catalog is the lack of the evaluation of spectrum quality and unclear terminology, e.g. using also some customary chemical names inconsistent with semantics, which led to a certain number of repeated spectra in the database (i.e. spectra of the same substance). The inconsistent terminology also excluded the possibility of cooperation between this database and other collections [e.g. carbon-13 nuclear magnetic resonance (^{13}C-NMR), proton magnetic resonance (^{1}H-NMR), MS, ultraviolet (UV)] which were created simultaneously with IR databases, and they stayed as monomethod manual

catalogs and related to computer libraries of molecular spectra.

Currently the world's largest database of IR reference spectra of organic compounds is the Sadtler Condensed Phase IR Standards Database. This database contains data on 75 620 different chemical compounds (http://www.bio-rad.com/626559.html). The IR spectra stored in the Sadtler collection are of very high quality. Each compound, before its spectrum is placed in the Sadtler collections, is prepared under standard conditions at Bio-Rad Laboratories, Sadtler Division, using equipment manufactured by leading instrument makers. Samples are checked to ensure that nonlinearity is avoided to maximize reproducibility and provide for the best subtraction of reference spectra. Wherever possible, Sadtler chemists verify every IR spectrum by checking the corresponding NMR and UV spectra. Any spectra which show evidence of composition impurities or reaction with sampling apparatus are rejected. Each spectrum is then reviewed by an independent consultant before inclusion in the database. These quality control procedures provide the best sample purity and structural formula confirmation available for the broad range of compounds in the collection. This database of spectra affords access to the spectra of compounds having desired functional groups and which can be used to establish an identity through empirical comparison. The Sadtler database includes spectra of most simple aliphatic, aromatic, alicyclic and heterocyclic compounds, and also numerous complex materials. Numerous series of homologous compounds, ranging from the very simple to the very complex, which allow spectroscopic studies of trends involving homologs, are also included. The Standards Database is also very useful for the establishment of complex chemical classes of undocumented commercial compounds with similar structures. The molecular structure symbol signifies the molecular structures associated with the database. The structures are available for viewing and substructure searching by special search software.

Apart from the Sadtler database mentioned above, other IR databases for pure organic compounds are also offered (see Table 3). Additionally, a number of dedicated computer collections of IR spectra have been developed, e.g. IR databases for polymers and related compounds, industrial compounds, forensic science, environmental applications and inorganic and organometallic compounds (see Table 3, http://www.bio-rad.com/620859.html).

Apart from the above-mentioned computer IR libraries, there are also IR databases provided by producers of

Table 4 Multimethod spectral computer databases containing IR spectra (a few examples)

Name of database/country	Number of spectra in spectral library					
	IR	MS	^{1}H-NMR	^{13}C-NMR	UV/VIS	Raman

IR spectrometers, e.g. a digitized version of *The Aldrich Library of FTIR Spectra*[42] (over 10 600 spectra), and *The Sigma Library of FTIR Spectra*[43] (over 10 400 spectra of biochemicals) as available exclusively from Nicolet Instruments GmbH, or *Bruker FTIR Libraries* (over 13 400 FTIR spectra) offered by Bruker Analytische Messtechnik GmbH.[44] The next step in the development of SDBs was to create multispectral databases. Most of them include libraries of IR spectra (see Table 4). The experience gathered during IR bases development helped in creating spectral bases for other spectral techniques. The content of a given multimethod SDB is usually presented as a list of individual catalogs (IR, MS, UV, etc.) and numbers of spectra related to them. The information about the numeric size of the collections in Table 4 is approximate, and it can differ from current numbers, as the databases are being continuously supplemented and transmitted between various scientific centers which include the new databases in their own collections.

3 STANDARDS IN INFRARED DATABASES

A very important matter for producers of IR databases (printed and computer collections) is to ensure high quality of the IR spectra. It is also important to define one unified data format for computer collections in order to assure accurate transportation of scientific data between different computer systems and software packages. Accurate transportation of data is an essential element of modern integrated laboratory work.[49]

The problem in the quality control of IR SDBs is connected with four main areas:[50] sample preparation, data handling, spectrometer performance and data presentation. With regard to the spectra in an IR collection, attention should be paid to the manner in which a given compound is prepared for an examination. The sample preparation procedures should result in obtaining a reproducible spectrum. The data handling of an IR spectrum downloaded by a computer needs to be controlled by an experienced person in order to avoid any loss of spectral quality and the introduction of any artifacts into the spectrum. Spectrometers used for the registration of reference spectra should be calibrated by standard samples. These three above-mentioned areas determine the quality of reference spectra. All guidelines for the collection of reference IR spectra are formulated by spectroscopic centers. For example, the Coblentz Specifications for IR Reference Spectra of Materials in the Vapor Phase above Ambient Temperature defines the best realistically obtainable spectra as ''reference spectra obtained on high-quality commercial instruments operated at maximum efficiency under conditions consistent with acceptable laboratory practice''. Their precise criteria for sample preparation, spectrometer working parameters and spectrum hard copy (e.g. range of spectrum registration, resolution, noise, baseline, recording continuous with no gaps in wavenumber, purged or evacuated spectrometer, linear abscissa in wavenumber, linear ordinate in absorbance, accuracy with sharp bands readable to 3 cm^{-1}).

In addition to sample and spectra registration conditions, the guidelines for collections of spectra elaborated by expert committees for the submission of spectra to the Spectrendatenbanken-Verbundsystem (Germany)[50] also accept the Joint Committee on Atomic and Molecular

Physical Data Exchange (JCAMP-DX) transfer format of spectral data presentation. McDonald and Wilks are the authors of the first JCAMP-DX standard for IR spectroscopy.[51] The JCAMP-DX is a standard format for IR, UV/VIS, NMR and mass spectra, whereas the Joint Committee on Atomic and Molecular Physical Chemical Structure (JCAMP-CS) format has been proposed for chemical structure coding.[52] The JCAMP-CS format provides definition for exchanging information on compounds and sterochemistry, and also on the two-dimensional (2D) and three-dimensional (3D) atom coordinates of chemical structures. Where possible, care was taken to make the conversion to other formats in use for representing chemical structures as simple as possible.

The JCAMP-DX format is an answer for those chemists who need a standard file format for the exchange of IR and other kinds of spectra between numerous vendor data systems which nowadays use various proprietary file formats. Unification will enable spectra to be transferred between different spectrometers from their own and other laboratories. The usefulness of the JCAMP data exchange formats has been recognized and accepted by such organizations as the International Union of Pure and Applied Chemistry Committee on Printed and Electronic Publications (IUPAC-CPEP) and ASTM (http://lolita.colorado.edu/faq). This leading standard is also used in SpecInfo SDBs. The implementation of the JCAMP standard as a transport format for IR spectra has been a great step forward in the direction of interlaboratory communication. However, the international organization of structural and spectral data storage and archiving has been a serious problem. Nowadays, software utility programs permit the conversion of different formats to the one which would be accepted by a given system. For example, the following formats (in addition to the JCAMP) are currently used in each of the software listed:

- Sadtler software: Galactic SpectraCalc/GRAMS, Digilab 3200/WIN-IR, Nicolet SX/DX/PCIR/OMNIC, Perkin-Elmer IRDM/1600/7000 and others (http://www.bio-rad.com/610483.html, http://www.sadtlersuite.com/spec.html);
- ACD/IR Manager: GRAMS, ASCII (http://www.acdlabs.co.uk/products/ir/ir_mgrhtml).

The open and flexible nature of the JCAMP standard and its easy electronic transmission not only on a PC but also in the Scientific and Technical Information Network (STN) International Network are the reasons why this standard will most probably become the most commonly used standard also by SDBs producers and instrument manufacturers.

According to various literature sources, parallel development of printed and computer IR databases can be observed. Owing to the low technological level of spectrometers, the first collections of IR spectra were often of poor quality. Contemporary IR SDBs contain spectra of a considerably higher quality owing to the advent of high-resolution spectrometers and proper sample preparation (according to the standards required).

In addition to large SDBs containing data on different chemical compounds, many collections dedicated to specialized groups of compounds are offered.

Recently, a new type of printed catalog of spectra has appeared on the market. The traditional form of a book is supplemented by a diskette containing peak tables in a digital format, allowing the reader to search for unknowns[19] (http://www.elsevier.nl/locate/isbn/0444826203).

As far as computer databases are concerned, many efforts are aimed at the unification of spectral and chemical structure codes, which will assist in the easy exchange of information between various scientific centers. IUPAC has additionally published a very positive opinion about the JCAMP format which makes it very probable that this format will be broadly used in the future.

4 STRUCTURE OF INFRARED DATABASES

In this section, some examples of the computer IR database structure is discussed. Since the late 1960s, various computer programs to automate the collection and processing of IR spectra have resulted in different forms of digital representation of spectral data, from the first binary code form[53] to the latest fully discrete form, e.g. OPUS software system (Bruker),[54] SpecInfo 3.2–Input Editor (http://cds3.dl.ac.uk/specinfo/ug_input.html) and Sadtler–IR SearchMaster (http://www.sadtlersuite.com/spec.html).

4.1 Information Stored in Spectral Databases

IR databases usually consist of the following data:

- *Compound identification database (CDB)*. Each record of the file contains the structural and alphanumeric information about a compound, such as systematic and trivial name, chemical formula, molecular weight, CAS registry number, bibliographic data and selected physicochemical parameters (density, refractive index, dipole moment, melting and boiling point, dielectric constant, etc.). Each of these data and their combinations can be used in searching a certain database in order to find all the information about a compound. Some of the input data (e.g. CAS registry

number, molecular structure) enable one to select the compound unequivocally; others (e.g. molecular formula, molecular weight) provide a list of substances fulfilling the introduced search parameters.

- *SDB*. In this database, separate information about the conditions of a spectrum preparation (instrument, temperature, sample preparation, solvent, frequency region, concentration, cell thickness, optical materials of cell, purity, vertical axis, horizontal axis, etc.) is stored in addition to details about the spectrum itself. In principle, each record contains spectral band parameters, a spectrum in a discrete form and usually also a quality index (QI). The value of QI[55] depends on compound purity, the method of sample preparation, the quality of the spectrometer used, etc.

The above data may be grouped in two separate files (CDB and SDB), but usually the structure of a database is much more complex, i.e. the database contains several files that are related to each other by cross-references.

The information about a structure may be input into a database either in an alphanumerical form (such as list of atoms and bonds and connectivity tables) or in a graphic form. An example of an alphanumerical form is the Wiswesser Line Notation (WLN) used in some Sadtler databases (http://www.bio-rad.com/629418.html) or the JCAMP-CS format accepted for chemical structure coding in the SpecInfo system (http://lolita.colorado.edu/faq).

The graphic program for a structure presentation offers easy molecule construction and provides a full range of structure input methods to be used by a chemist. Chemists can easily draw any structure using a mouse and the program's interactive sketch function (see Figure 1). Usually when drawing carbon, hydrogen atoms are automatically labeled. The introduced structure is coded

Figure 1 Example of structure edition in computer system.

and changed to a canonical form. This step is necessary because several different pictures of the same structure exist; the canonical form assigns them all the same code, in which the structure is stored in an SDB. Structural information is the most important of the CDB data as it starts the creation of a record for a given compound. Other CDB information can be input optionally.

4.2 Spectrum Representation and Spectral Database Organization

Many systems for archiving collections of spectra on a hard disk (documentary function) have been developed. They give access to information about the structure, spectra and physicochemical parameters of organic compounds, stored in an SDB (information function).

The basis for many computer collections was the ASTM catalog,[11] in which every IR spectrum is presented in a binary (0,1) code generated in the following way: the whole range of a spectrum registration was divided into 0.1 μm intervals; if there was an absorption band in an interval, the interval was given the value 1 and the lack of a band was coded with 0. The virtues of the binary coding form are that it can be stored in a small section of a computer memory (each figure of the code is stored in one bit of memory), and it gives the possibility of using fast algorithms of spectral comparison. The disadvantage of this method is the lack of information about real absorption band parameters (location, intensity and shape).

The development of various computer systems initiated remarkable progress in the creation of molecular spectral computer databases. It was possible to store more information about a spectrum in the databases, which led to changes in the type of data to be stored. The following types of data would be stored:

1. data on the number and location of bands in each spectral coding interval;
2. data on the location of all the bands in a spectrum;
3. data on the location and intensity of chosen absorption bands;
4. data on the location, intensity and factors defining the shape of bands in a spectrum.

None of the mentioned spectrum coding methods would permit the reproduction of a graphic picture of a spectrum. Completion of the already existing spectral data with factors defining shapes of spectra enables one to calculate their curves and finally to display a given spectrum on a monitor screen. Hence the user of the system can compare the analyte spectrum and a spectrum found in the database. The shape of an absorption band can be reproduced by means of a factor called the half bandwidth and an approximating function (in the most general

case it is a sum/product of Gaussian and Lorentzian functions[56]). Other additional parameters can be directional factors of lines approximating absorption band shapes.[57]

Nowadays, the most commonly used method of spectral coding is via the intensity values of spectral curve points with a constant step of discretization. This method demands a substantial memory for the database. A discrete spectrum code is a set of intensity values coded for a constant step of changes for the horizontal axis. In the database, only the information about the values of the intensity of points will be stored.

The possibility of coding whole spectra in a discrete form in a database appeared first in the late 1970s, together with disseminating magnetic carriers of a large capacity and with the possibility of fast access to the stored data (magnetic disks). Additionally, providing spectrophotometers with computers permitted spectrum archiving in real time (on-line), simultaneously with the analysis being conducted (see Figure 2). Usually, each spectrometer is connected only with its own PC computer, but in some laboratories spectrometers are linked together in the LIMS network,[58] which facilitates the creation of a multispectral data bank.

The generation of a molecular spectral library is carried out as shown in Figure 3. Nowadays, the source data are usually transmitted to a computer directly from an analytical instrument (the on-line method). In exceptional cases, the computer databases must be updated by spectra recorded only in an analog form[59] (such spectra were registered by old types of spectrometers, or the data were taken from the literature), and then a digitizer must be used (the off-line method). The spectra stored in a database are supplemented with additional information about their discretization process. They are also transformed according to the format of given library data. All these spectral data (Figure 3) are compatible with any database management program. Most computer systems demand input data prepared in the JCAMP-DX format to be able to build any IR database. A description of the JCAMP file structure can be found on the Internet under http://members.aol.com/rmcdjcamp/xydatst.txt.

Figure 2 Scheme of Laboratory Information Management System (LIMS).

Figure 3 Numerical preprocessing scheme of IR spectrum.

An example of the input IR spectral data is presented in Table 5. The format of the data coded in each line is specifically defined. The JCAMP-DX format accepts three values for step discretization of an IR spectrum (e.g. ##DELTAX = 1.0, 0.5 or 2.0 cm^{-1}). The step of spectrum discretization is a very important parameter in spectrum representation. To choose the optimal step of discretization, the authors of databases take the purpose of the creation of the set of spectra into consideration. If a database is to be a set of references and spectra are to be processed, this step must be smaller (0.5 or 1.0 cm^{-1}); it can be bigger when a set is created only to display an image of a spectrum on the screen, or when only information on whether the database contains a given spectrum is needed. Although the discretization step is a very important parameter in evaluating the quality of spectra stored in a computer database, only few authors publish any information about the size of the step, i.e. the resolution for data exchange files. Such information can be found, for example, in the manuals on the Sadtler databases or on the SpecInfo system.

The use of a spectrum in a fully discrete form is often difficult for LS algorithms, e.g. for the structure identification of an unknown compound. Therefore, in some databases[37,38,60,61] for fast searching, apart from spectra in a discrete form, tables of absorption band parameters calculated from spectra (location, intensity, etc.) are also stored. If a discrete spectrum form is also stored in a computer mass memory, it enables one to display a real spectral curve on a monitor screen. In this case, the optimal number of discretization points depends on the resolution of the monitor (on the number of pixels).

Table 5 Example of JCAMP-DX format for IR spectra

Line format	Remarks
##Resolution = 2	Spectrum resolution
##Deltax = 1.0	Discretization step = 1 cm^{-1}
##Xunits = 1/cm	Wavenumbers
##Yunits Transmittance	Intensity units
##Xfactor = 1.0	Representation of the actual decimal value *x*
##Yfactor = 0.0001	Representation of the actual decimal value *y*
##FirstX = 400	First *x* value
##LastX = 4000	Last *x* value
##NPoints = 3601	Number of discretization points
##FirstY = 0.4480	First *y* value
##XYdata = (X++(Y..Y))	X++ indicates symbolically that each line of data starts with an abscissa value which is incremented between ordinate values. Y..Y indicates that the remainder of each line is filed with a series of ordinate values. The actual data ##XYdata = starts on the next line (400 4480 4618, ..) is a table of ordinates at equal X-intervals
400 4480 4618 4716 4788 4838 4850 4806 4680 4446 4126 3748	
411 3324 2852 2342 1827 1354 953 625 387 251 242 381	
...	

Calculating the values of absorption band parameters is one of the most difficult issues in numerical analysis owing to the complicated character of molecular spectra, which consist of many overlapping absorption bands.

In the 1970s and early 1980s, the problems of the mathematical elaboration of spectral curves were widely discussed in the literature,[56,62–67] connected with problems of structural identification. Many different solutions and detailed numerical algorithms were presented, the most important of which seems to be the algorithm created by Jones et al.[56,64,65] Their numerical algorithm (for calculating the values of absorption band parameters) considers eight basic operations of mathematical spectra elaboration, namely:

- numerical spectrum transformation;
- scale calibration;
- scale correction and transformation;
- numerical filtration;
- deconvolution;
- recognition of overlapping bands;
- localization of isolated and overlapped bands;
- calculation of real parameters of spectral absorption bands.

Commercial software [e.g. PeakFit (http://www.spss.com/software/science/peakfit), STATISTICA (http://www.statsoftinc.com), Galactic GRAMS/386,[40] OMNIC FTIR[40]] works with the above numerical operations for spectrum curve processing.

The software managing commercial SDBs provides access to information included in the databases in order to enable one to use it, but any changes to the information are impossible, as the databases are protected against any interference. Nevertheless, the user can additionally create his or her own database, e.g. by on-line methods, when the spectrometer is directly connected to the computer. Thus, the user has two SDBs available: the commercial one (only for searching) and a personal library. The user has direct access to the user-defined database(s), and can take one of the following actions: add new data, delete data, correct data and delete the whole database. Hence the spectroscopist has a tool for the documentation of his or her work and for the identification of compounds which are present in his or her personal SDB. The commercial databases are enlarged by successive upgrades on a PC or by access to a network data bank, disseminated for users.

As the IR curve depends strongly on the method of sample preparation (e.g. KBr pellet, liquid film, solution in a given solvent, vapor), the storage of several IR spectra for one compound is useful when an SDB is applied to studies concerning the influence of spectrum registration conditions (temperature, pressure, concentration, etc.) on band location and band intensity. In this case, a single structure of a compound is stored and is connected by the cross-references with all its spectra. Special procedures enable one to compare various spectra in order to observe any differences between them. Such a solution is applied in the SCANNET system, with which one can gather five different IR spectra (of one compound) obtained under different conditions. The system also enables observation of the phenomena[61] that cause changes in the spectral band shape and also the disappearance and/or appearance of the bands. The investigation of the phase transition of dichloromethyl *tert*-butyl ketone is shown in Figures 4–6.

Figure 4 IR spectrum of the crystalline form of dichloromethyl *tert*-butyl ketone.

Figure 5 IR spectrum of the liquid form of dichloromethyl *tert*-butyl ketone.

Figure 6 Overlapping and differential IR spectra of dichloromethyl *tert*-butyl ketone.

Figure 7 IR spectra of allyl phenyl ether (bottom) and *o*-allylphenol (top).

Figure 8 Overlapping and differential IR spectra of allyl phenyl ether and *o*-allylphenol.

The IR spectrum of the crystalline form of the substance is presented in Figure 4 and Figure 5 presents part of the IR spectrum of the liquid form. It can be seen from the overlapping spectra and from the differential curve (see Figure 6) that the spectrum of the substance in the liquid phase contains only one band at 797 cm^{-1} instead of two bands at 799 and 778 cm^{-1}, characteristic of the crystal phase.

The storage of different spectra for one compound can be used for studies of the Claisen rearrangement of allyl phenyl ether to *o*-allylphenol is shown in Figures 7 and 8. On these figures one can observe a strong band at 3430 cm^{-1} (due to the stretching of the O–H bond of the hydroxyl group) in the product spectrum, which is absent in the substrate spectrum.

5 RECOGNITION OF CHEMICAL COMPOUND STRUCTURE

Many attempts have been made in recent years to make the structure elucidation process faster and more reliable by using computers. All the methods presented below (LS algorithms, correlation tables method and neural networks) use IR databases.

The structure of these databases differs for each of these methods. The LS method works on large (tens of thousands) collections of spectra and enables one to find in a database a set of compounds identical with or similar to the analyte compound.[68] In the case of the other two methods, a database is used on a level of generating the identification system. When the correlation tables method is applied, the IR spectral library

(containing from several hundred to several thousand spectra) is used to generate a knowledge base consisting of spectra–structure correlations (presented as tables, interpretation rules or decision trees). The generated knowledge base, together with the inference engine, forms an expert system for structural fragment recognition. The last method uses one specially transformed IR database to learn (to train) how to recognize chosen structural fragments. Once a network has been trained, it is able to identify the fragments without using the IR spectral library.

5.1 Library Search Algorithm

The identification of a chemical compound structure based on the application of an IR library consists[68–71] in looking for the identity or similarity between the spectrum of an unknown substance and one or more spectra from the standard collection. The reasoning is based on the logic Clerc cycle[72] (see Figure 9) assuming that the identity or similarity of the examined and reference substances spectra proves the identity or similarity of their structure. Obviously, some assumptions which would enable one to realize an inference process must be fulfilled (the same method of sample preparation, the same coordinates, similar spectrometer settings, etc.). The control of the data stored in a database is particularly important, as the shape of an IR band is strongly dependent on the mentioned parameters. Therefore, the algorithm comparing the spectra should be preceded by the control of spectrum registration conditions. This algorithm LS algorithm is based on a known paradigm of artificial intelligence – ''describe-and-compare''.[73] The LS algorithm imitates the reasoning of a chemist, who elucidates the structure of a chemical substance by comparing its IR spectrum with successive spectra of known compounds stored in a database. In the case of an automatic (computer) realization of the LS algorithm, not the whole spectral curves are being compared, but only some selected spectral features, so the algorithm for calculating the measure of the identity/similarity of the features must be defined.

It is assumed that for spectral features being compared, one of the following relations exists:[69]

Figure 9 The logical cycle of Clerc.

selected spectral feature	do not inconsiderably considerably	changes for
identical similar different	structures	

These relations are realized according to detailed solutions accepted by a given author. Generally, the LS algorithm is realized in the following steps:[68]

1. the conversion of an unknown compound spectrum into a digital form, exactly the same as that used for reference spectra in a database;
2. the sequential comparison of the numerical representation of an unknown spectrum (of an analyzed compound) with successive spectra in a database;
3. the output of information about the results of searching the database, i.e. a list of spectra identical with or similar to the analyte spectrum, on the basis of a predefined criterion for spectral similarity (strictly, similarity of numerical representations).

The list of these spectra is usually sorted according to decreasing values of their fitting factor, which is a measure of spectral similarity. A value of the fitting factor of 1 refers to complete identity of the spectra being compared, whereas a value of 0 implies a lack of any similarity between them. A chemist is the one to take the final decision about which of the structures proposed by the program is that sought. The LS method of the identification of unknown compounds from their IR spectra has been widely applied for practical purposes. Now, every FTIR instrument has functions for database searches on its minicomputer. However, the success of the database search method depends on the size of the database. That is, in order to identify an unknown spectrum, its precise (or highly similar) reference must be included in the database. However, when the size of the database becomes larger, the search will take longer, which is especially critical in the case of systems on PCs. For this reason, with neural network application a new technique for faster searching of IR databases was elaborated.[74]

An example of a real procedure for the elucidation of an unknown compound structure aided by a LS method is shown in Table 6 and Figures 10 and 11.[75] The unknown compound was identified by means of the IR spectrum. The IR spectrum in a discrete form was the input data; the spectral bands selected for searching are presented in Table 5. After searching the IR database, a list of substances having IR spectra identical with or similar to the input spectrum was obtained. The list contains one compound with a fitting factor of 1.0 (1-pentanol) and

Table 6 Example of IR database searching

Input band parameters	List of substances identical with similar to unknown compound		
	No.	Name of compound	SI
3382–3342 (cm^{-1})	1	1-Pentanol	1.00
1.037–2.387 (Å)	2	1-Hexanol	0.94
	3	1-Butanol	0.94
	4	2-Octanol	0.82
2985–2945 (cm^{-1})	5	2-Methyl-1-pentanol	0.82
2.787–2.387 (Å)	6	1-Heptanol	0.82
2893–2853 (cm^{-1})			
1.513–1.113 (Å)			
1477–1457 (cm^{-1})			
0.536–0.336 (Å)			
1470–1450 (cm^{-1})			
0.480–0.320 (Å)			

SI, similarity index; 1 Å = 10^{-10} m.

Figure 10 Overlapping IR spectra: (1) unknown spectrum; (2) 1-pentanol.

Figure 11 Overlapping IR spectra: (1) unknown spectrum; (2) 1-hexanol.

others with fitting factors <1.0. Overlapping IR spectra are presented in Figures 10 and 11. Here, the unknown compound and 1-pentanol are identical, whereas the spectrum of 1-hexanol differs slightly from the unknown spectrum (fitting factor 0.94). The analyte compound therefore has the structure of 1-pentanol.

The weakness of the LS approach is related to the necessity for a powerful computing system and a large database. Also, even a large database may not contain identical or very similar reference spectra with respect to the sample spectrum. The LS method can thus solve the problem of structure identification when the database contains a spectrum identical with (or very similar to) the sample spectrum. Otherwise, to elucidate the structure of an unknown compound it is necessary to use methods that permit the recognition of structural fragments present in the molecule of the analyte substance. The IR library can also be applied to discover spectrum–structure correlations.

5.2 Discovering Spectrum–Structure Correlations from Infrared Databases

A different approach in spectral interpretation is based on the determination of functional groups which may be present in an unknown compound. Several computer programs have been written in order to mimic the human process of interpreting an IR spectrum of an unknown compound. These programs[76,77] use correlation tables (a list of structural fragments and their spectral characteristic parameters) which can form a knowledge database or be an integral part of the program. Usually, these parameters are taken from literature,[73–88] but they

can also be generated from a computer library of IR spectra.[77,86,89,90] The first approach of using information from the literature was applied in the X-PERT system,[88] which contains a set of molecular fragment libraries and the spectral features of fragments (for IR spectroscopy, the ranges of characteristic frequencies, intensities and band half-widths). For example, the CH_2=CH– group is described by four diagnostic intervals: 880–900, 1395–1440, 1640–1655 and 3010–3120 cm^{-1}. The second approach[86,87] consists in generating spectra–structure correlations from a computer library of IR spectra, which is an automated knowledge acquisition from an IR database. The acquisition of spectral information is done in order to create rules allowing the identification of molecular fragments of an unknown compound from its IR spectrum. The process of searching for spectrum–structure correlations can be realized by computer-simulated neural networks,[89,90] by application of a statistical algorithm[77] or by the combination of a statistical algorithm with an algorithm related to the set theory.[86] The statistical algorithm (see Figure 12) splits the database into subsets with and without a given substructure. Next, it divides the IR spectral range into intervals, and counts the number of spectral features (absorption bands) present in the spectral intervals separately for each subset. Then, the normalized histograms (confidence factor (CF) for each interval) for both subsets are calculated. The difference between these histograms (interpreted as being the effect of only some characteristic spectral features) is converted into correlation tables. After their evaluation by a chemist, the correlations are automatically transformed into rules for substructure identification, a set of rules form a knowledge base being a part of the expert system for structure elucidation.

The basic lemma of the algorithm relying on the set theory applied by Ehreintreich et al.[86] is that every compound containing a substructure S must contain at least one absorption band in every characteristic interval described by a subset of the spectroscopic features: band location, intensity or half-width. This lemma is necessary with respect to strong logical conclusions but it is not fully justified with regard to excitation rules in IR spectroscopy (e.g. problem of center of symmetry). The core of the algorithm lies in a search for a large set of intervals as small as possible. The correlation obtained by these two algorithms can be finished manually by comparison with literature data and next transformed into a rule base for interpretation of IR spectra.

The application of this statistical algorithm for the generation of spectral correlations is presented for the amine group (see Figure 13a–c). The histogram has been plotted as a statistical area diagram using location (cm^{-1}) and CF as coordinates. The rectangular

Figure 12 Algorithm corresponding to automatic knowledge acquisition from IR database.

height corresponds to the diagnostic power of the spectral interval. From among all the components of the diagnostic vector (see Figure 13a), the components of the maximum value components (CF < 20%) were chosen (see Figure 13b). Next, they were converted into correlation tables of the investigated substructure (see Figure 13c). One can see (see Figure 13b) that for the $-NH_2$ substructure three diagnostic regions fulfill these conditions. In the first region four intervals (Nos 1, 2, 4 and 5; yellow) were classed, in the second two intervals (Nos 3 and 7; gray) and in the third one interval (No 6; white).

The result of searching for structure correlations depends strongly on the IR database used in the process of searching. The spectral ranges generated from an IR database containing spectra of various types of chemical compounds are wider than the relevant ranges obtained by using dedicated bases (IR collections of carboxylic acids, hydrocarbons, etc.). The interpretation rules are of the general form

IF *conditions* **THEN** *hypothesis*

The *conditions* may be represented by logical expressions:[77,86,88] **A AND B**; **A OR B**, where A and B are the spectral features. In the *hypothesis* represented by logical expressions **C AND D**; **C OR D**, symbols C and D are the substructures identified by A and B spectral features. Thus, the rules can have the form:

IF A THEN C; **IF A AND B THEN C**;

IF A OR B THEN C AND D, etc.

(c)

Figure 13 Spectrum–structure correlations generated for $-NH_2$ substructure.

A standard example of the substructure identification rule is as follows:

IF band_location ∈ interval_frequency[1]
AND band_intensity ∈ interval_band_intensity[1]
. . .
AND band_location ∈ interval_frequency[n]
AND band_intensity ∈ interval_band_intensity[n]
THEN substructure **IS** present

where n = number of the bands characteristic of the analyzed substructure.

This type of rule (related to spectral correlations) is then augmented by a set of rules required to control the inference engine, steering the way of reasoning and output of obtained results. The complete knowledge base

Figure 14 Block diagram of classification algorithm.

generated is in the next step compiled and used by the reasoning section of an expert system. During the consultation, the user enters spectral parameters (band locations and intensities) of the spectrum of an unknown compound. The inference engine accessing the knowledge base generates the list of substructures that would possibly constitute building parts of the investigated structure (see Figure 14).

5.3 Neural Networks as Tools for Structure Recognition

Apart from a LS,[91,92] the use of correlation tables and many different pattern recognition techniques, and also the application of computer-simulated neural networks (abbreviated to neural networks) working on a base of an encoded spectral collection, has been attracting increasing interest in the last few years. The main purpose of this method is to extract structural information from spectral data;[93–105] however, neural networks have also been used for predicting spectral features (i.e. for simulating spectra) from a chemical structure,[90,94,95,106,107] and also for the identification of IR spectra, i.e. to find in the IR spectral library a spectrum identical with the analyte spectrum[74] (the alternative approach to the LS method).

Neural networks[96] are known to be able to learn and then to recognize patterns, so neural networks constitute a means of pattern classification in which an input pattern (a vector the values of which represent object data) is transformed into an output pattern (a vector the values of which represent the desired classification of the object data). In structure elucidation, the input pattern is a representation of an IR spectrum of an unknown compound and the output pattern is a representation of functional groups (substructures) present or absent in the compound. The transformation is achieved by a propagation equation which combines the input vector with coefficients internal to the network. The coefficients are generated by a process called *training* or *learning*.

Starting from random values of the coefficients, output vectors are calculated from a set of input vectors (encoding IR spectra) for which the ''right answers'' (presence or absence of recognized groups) are known, the right answers being encoded in a target vector. After the calculation, a learning rule uses differences between the output values being obtained and target values to modify the coefficients. As this process is repeated, the coefficients gradually converge to values which transform each input pattern to an output pattern closely conforming to the target. Once a neural network has learned to recognize the given substructures, it can be used for the *prediction* of the presence or absence of these substructures in an unknown compound from its encoded IR spectrum.

For substructure recognition, the most commonly used approaches are ''error-back-propagation'' learning methods in multilayer neural networks, and two simple architectures, mono- and multioutputs. Mono-output networks are specialized networks trained to recognize only one particular substructure, whereas multioutput networks are trained to recognize simultaneously several substructures from a single input vector. The hierarchical system[105] of neural networks is half way between one large neural network with many outputs and many mono-output networks. In most work a digitized spectrum was the spectral information used as a network input, so that the number of input elements can vary between approximately 100 and 4000 (for an IR spectrum it is usually about 256 or 512 elements). Another means of spectrum encoding[96] is to divide a spectral range into intervals, assigning each interval to an input unit, and giving for the unit a nonzero value if a band occurs in a frequency interval, or zero otherwise.

An example of the application of neural networks to substructure prediction is the work presented by Novič and Zupan.[90] A training set of about 755 IR spectra was selected from the IR database using the Kohonen layer in a neural network. The spectra in the range from 3500 to 550 cm^{-1} are coded as 512 intensity points, which after Hadamard transformation are reduced to 128 intensity values (1 : 4 reduction). The structures of compounds included in a training set of spectra were coded as 34-dimensional binary vectors. The ones and zeros correspond to the presence or absence, respectively, of a particular fragment (34 structural fragments were defined and coded; see Table 7). These coded IR spectra and structure vectors corresponding to them were the input data to the neural network. It was assumed that the network after a training process will be able to recognize the presence or absence of these structural fragments in a molecule of an unknown compound from the compound's IR spectrum. The counterpropagation neural network, i.e. a two-layer network consisting of a Kohonen and an output layer, was used in the training process. The learned (trained) network was tested on a database of 2529 IR spectra (encoded in the same way as the training spectra set) of known substances. The prediction correctness was calculated and evaluated separately for two sets, a set of compounds containing the tested substructure and a set of compounds without this substructure. The evaluation of the neural network's predictive features was dependent on the number of substructures identified correctly. ''Correct identifying'' means that a given substructure was recognized in a structure of which it was really a part, and it was not recognized where it did not exist. The highest prediction correctness was for the groups carbonyl (96%), carboxyl (94%) and hydroxyl in alcohol (93%). Poor prediction results of less that 35% were obtained for furan (31%), CBr (30%), thiophene (19%) and CI (0%). It can be concluded that the vibrations caused by these and similar fragments are not significant in the IR region, or their influences on IR spectrum are lost among other (more dominant) spectral features.

Very interesting work concerning the correlation of IR spectra with a molecular structure were presented by Gasteiger's group.[106–110] The most important achievement was the successful application to spectrum–structure correlation problems of a novel and original way of coding 3D molecule structures. It is based on equations used in the analysis of the intensity distribution, which can be obtained in electron diffraction experiments. Structure coding and inductive learning algorithms allow one to store the relationship between the 3D structure of a molecule and its IR spectrum in a neural network. The relationship is stored in the weights of a counter-propagation neural network. Such a network is able to simulate an IR spectrum by inputting the coded structure of a molecule. On the other hand, a structural code of a molecule can be predicted by inputting an IR spectrum. As the second step, this structural code can be decoded to obtain Cartesian coordinates of the atoms in the molecule.

A number of authors proved that computer-simulated neural networks provide a practical method for detecting the presence and absence of functional groups on the basis of IR spectral data. Thus, the neural network can be used as a program for structure determination of an unknown chemical compound, and can also cooperate with an expert system for structure elucidation.[89] The combination of a neural network and an expert system can be used in two distinctly different manners. In the first, the network is used in cooperation with an expert system to analyze an unknown compound; in the second, the network is used to help in the creation of rules which the expert system will use. In the first case, the neural network is used directly and simultaneously in connection with the expert system, and the conclusions about the presence

[a] $^{+}p_i$ = fraction of correct prediction for compounds containing substructure number i (fraction of recognized substructure).
[b] $^{-}p_i$ = fraction of false prediction for compounds containing substructure number i (fraction of unrecognized substructure).
[c] R_i = reliability of substructure recognition, $R_i = 2(^{+}p_i - {}^{-}p_i)/(1 + |^{+}p_i - {}^{-}p_i|)$.

(or absence) of a substructure are entered into a database of facts which are then used by the expert system. In the second case, the neural network can be used indirectly, providing information (extracted from the coefficients of the network) which enable one to fix the correlations between the substructures and their spectral features. The correlations can next be taken into consideration when writing the rules for the expert system.

6 MULTIMETHOD SPECTRAL DATABASES

The computerized processing of spectral information has become a routine procedure for many laboratories in the last few years. The use of artificial intelligence to combine spectral information obtained by various spectral techniques is essential for the determination of a chemical structure. It is a more efficient solution than the application of only one spectral method because the results obtained by using different spectral techniques will be more accurate than when only one technique is used.

Multimethod SDBs (also called spectral data banks) contain some general information on chemical compounds (see section 4.1, definition of CDB) and/or on bibliographic references, as also monomethod databases obtained by use of various spectral techniques (see Table 4).

In this section, only spectral data banks containing also IR databases will be discussed. Each of the databases uses

a number of special programs, generally specific to a single spectroscopic method, for spectral data analysis and interpretation. The identification of a compound structure consists in the analysis of the results acquired from searching within separate databases, and the results can be combined to increase both scope and accuracy.[104] This function can be fulfilled by the main managing program summing the results of separate database searches. Usually, these results are shown as a list of compounds having bands identical with or similar to those for the examined compound. Finally, a global list including compounds present in all individual lists is created. Multimethod analysis provides more reliable results (higher SI) than the application of only one spectroscopic method. For all the compounds in a global list, all the spectra must comply with the requirements of similarity, i.e.

$$\text{global list} = (\text{IR list}) \text{ and } (^1\text{H-NMR list}) \text{ and } (\text{MS list})$$

Another procedure enables the user to select a different way of creating the global list, e.g.

$$\text{global list} = (\text{IR list}) \text{ and } [(\text{Raman list}) \text{ or } (\text{UV/VIS list})]$$

The chemist can choose ''and/or'' logical symbols and modify the search method according to his or her knowledge of the problem. If it is not possible to create a common results list (structures of a high SI), a list of substructures apparently occurring in the examined compound is built. Next, the probable structures and their spectra are generated. The calculated and experimental spectra are then compared with each other to choose the right structure from the candidate structures set.

Multimethod SDBs can be built by linking some spectral libraries with the already existing databases. The libraries can be obtained from industrial or university laboratories and also from various publications. Before being introduced into the bank, these data are carefully checked and transformed into a standard form. A multimethod system built in such a way includes databases which are not directly linked with each other. As a result of such system searching, separate structure lists are obtained. For example, Bio-Rad offers two Sadtler PC software products [i.e. IR Search Master version 3.0 and NMR Search Master version 3.1 (www.bio-rad.com/610441.html)] for searching various collections of IR and ^{13}C-NMR spectra.

One of the most important multimethod integrated SDBs is SpecInfo, which was developed by BASF for in-house use.[48] Actually, the SpecInfo system is available both as an in-house system through Chemical Concepts (www.dl.ac.uk:800/CDS/spectro.html) and for on-line use through the STN International (www.wiley-vch.de/cc/si_onl.html). The SpecInfo databases are updated thanks to the cooperation between the two experienced partner institutions [the Institute for Spectrochemistry and Applied Spectroscopy in Dortmund (IR and NMR spectra) and the Max-Planck-Institut für Kohlenforschung in Mülheim (mass spectra)[60]]. The SpecInfo on-line version provides information on chemical structures together with spectral information. It permits more than simple similarity searches and provides several run packages to assist users in important structure elucidation matters. For IR spectra, SpecInfo offers various search modes which may be performed using either the complete spectrum or just some of its defined ranges. Recent enhancements include cross-links to the CAS registry and the Beilstein Database.

Another example of multimethod SDBs, with entries connected through the structures of chemical compounds, which allows simultaneous access to all kinds of spectra stored for a given compound, is the Sadtler system. A user-friendly option gives the possibility of observing all the available spectra on a common screen. This option was adapted from, among others, the Sadtler User Library, the Main Manager program of which makes possible full viewing, plotting and coordination of IR and UV spectra, chemical structures, physical properties and bar charts for NMR and mass spectra, all in a sample spreadsheet format.[47] Another example of this kind of system is SCANNET, which assumes that within the identification methodology the results of a given randomly selected spectral interpretation (IR, MS, etc.) should influence the process of subsequent spectral interpretation through the cascade of facts logic.[71] This notion stands for the integrated interpretation of various molecular spectra of a given compound by the logical conjunction of intermediate analyses. The successive steps of the algorithm (see Figure 15) are as follows:

1. selection of a spectral method (i.e. SDB);
2. input of selected absorption band parameters and (if there is access) input of a spectrum in a discrete form;
3. searching the database for input absorption bands; the structure recognition of an unknown substance is made by comparing the input spectrum with

Figure 15 Block diagram of ''cascade of facts logic'' algorithm.

Table 8 Identification of an unknown compound by multispectral database

Cycle no.	Selected spectrum	Input band parameters	Number of compounds found in database	Global list		
				No.	Name of compound	SI

T = transmittance; – = scale of intensity value is relative.

successive reference spectra of standard compounds (chemical compounds of a known chemical structure) stored in a SDB;

4. creation of the global list and analyzing the final list of chemical substances for which the spectra are identical with and/or similar to those of the compound being searched for;
5. the end of a structure elucidation (see Figure 15, STOP command), if the output list satisfies the chemist; he or she can reinterpret the results by presenting the overlapping spectra on one screen and deciding to repeat the search process, choosing (a) new spectral methods or (b) other spectral band parameters.

An example of the use of the cascade of facts logic[46] is a structure recognition of an unknown compound led only on a basis of IR, mass and Raman spectra. The identification is realized in three subsequent cycles. When the investigated structure does not exist in a database, the chosen spectra have a SI smaller than 1.0 (see Table 8). If the process of searching an SDB gives a list of similar spectra, the result of the investigation is a hypothesis about a possible structural similarity between

Figure 16 Structures of compounds with the largest degree of similarity of spectra.

the structure of the unknown compound and one or several structures from the obtained list of similar spectra, depending on the SI. The result of the process of IR, mass and Raman spectra interpretation, three proposed structures, is presented in Table 8 and Figure 16. In the first cycle of recognition, the identification was carried out using only the IR spectrum, as a result of which 25 compounds (column c, global list) were found similar to the examined one. In the second cycle, the MS database was searched and 20 compounds (column c) were found similar to the analyzed substance. The comparison of the two lists (IR and MS) reduced the number of candidate compounds to seven substances (column d, global list). In the third cycle, similar analyses were performed for Raman Spectroscopy. From the Raman database 53 spectra were selected as similar to the Raman spectra of the unknown compound. Comparison of the Raman list with the IR and MS global lists reduced the number of candidate compounds to three. All spectra of the selected compounds (Figure 16) are similar to the analyzed compound's spectra, with *n*-butylbenzene being identified as the most similar one (SI = 0.93). As shown, the compound was univocally identified. All spectra of the compound stored in the system database can be seen on one screen (see Figure 17).

ACKNOWLEDGMENTS

The authors are especially grateful to Professor D. Cabrol-Bass (Nice–Sophia Antipolis University, Nice, France), Professor M.E. Elyashberg (All-Russia Research Institute of Organic Synthesis, Moscow, Russia), Professor L.A. Gribov (V.I. Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, Moscow, Russia), Professor Z.H. Hippe (Rzeszów University of Technology, Rzeszów, Poland) and Professor J. Zupan and Dr M. Novič (Institute of Chemistry, Ljubljana, Slovenia) for the reprints of their papers, which were a great help in our work on this article.

We express special acknowledgment to Professor J.T. Clerc (University of Berne, Swiss Federal Institute of Technology, Zurich, Switzerland) for his great interest, encouragement and help in our work.

We appreciate the support of the State Committee for Scientific Research (Warsaw) with Grants 8 8308 92 03 and 8 T11C 004 09 to assist our research in the field of IR SDBs.

Sum frequency generation (SFG) vibrational spectroscopy is a nonlinear optical vibrational spectroscopy, which has been shown to have submonolayer surface sensitivity. It has been developed into a powerful technique to investigate molecular structures of surfaces and interfaces. This paper introduces the technique of SFG spectroscopy and discusses several important SFG applications. One of the most important advantages of SFG over many traditional surface-sensitive techniques is that SFG does not require high vacuum to operate. Therefore, it can be applied to investigate liquid surfaces and interfaces, as well as interfacial biological molecules in biologically relevant environments. The SFG applications discussed in this article are (i) simple liquid surfaces and interfaces, (ii) polymer surfaces in water and polymer/silane interfaces, and (iii) interfacial structures of peptides and proteins.

1 INTRODUCTION

The chemistry at surfaces and interfaces is important for everything from high-tech industry to everyday life. The usefulness of many common items is determined by surface properties, for example contact lenses must remain wetted, while raincoats are designed to be nonwetting. The chemistry of surfaces has been tailored for many applications including antibiofouling surfaces for marine vessels, high-temperature-resistant surfaces for space shuttles, and heterogeneous catalysts.

Surface chemistry is also important in biology. The human body contains many different surfaces that are vital to our well-being. Surface chemistry is responsible for protein interactions with cell surfaces, hormone-receptor interactions, and lung function for example. To understand functions of biological molecules at interfaces inside our bodies and to prepare surfaces of advanced materials with desired properties, it is essential to understand the molecular-level structures of these surfaces in situ.

Excellent research on many surfaces and interfaces has been performed using a wide variety of analytical techniques.[1,2] However, many challenges still exist in the field of surface analytical chemistry. Many of the standard surface analytical chemistry techniques such as X-ray photo electron spectroscopy (XPS), secondary ion mass spectrometry (SIMS), scanning electron microscopy (SEM), and scanning tunneling microscopy (STM) require high vacuum to operate. These techniques are powerful surface-sensitive analytical tools, but it is difficult to apply them to the study of liquid surfaces/interfaces or buried solid interfaces.

Various techniques have been researched to study surface structures in liquid environments. For example, freeze-drying XPS has been developed to study polymer surface restructuring in water,[3] under the assumption that the freeze-drying process would not alter the polymer surface structure and thus the polymer surface will have the same structure as that in water. Such a method only provides surface elemental analysis rather than surface functional groups.

Contact angle measurements are easier to perform and can be used to study surface hydrophobicity.[4,5] Many surfaces (e.g. polymer surfaces) restructure when they are exposed to water, but contact angle measurements cannot provide a molecular-level picture of how the polymer surfaces change. These changes should have a molecular origin; that is, they are thought to be caused by the migration or reorientation of groups, segments, or side chains relative to the aqueous phase to minimize the interfacial free energy. Atomic force microscopy (AFM) has been used to study surface morphologies and surface properties (e.g. friction or adhesion) of many materials in a variety of chemical environments including aqueous solutions with excellent spatial resolution, but AFM cannot probe surface chemical structures.[6,7] Different theoretical models have been developed to simulate the details of the surface restructuring in water for decades, but the models need to be verified by molecular-level experiments.

Those techniques that can provide molecular-level structural information and do not require high vacuum, such as attenuated total reflection Fourier transform

Encyclopedia of Analytical Chemistry R.A. Meyers (Ed.)

infrared (ATR-FTIR) spectroscopy and surface enhanced Raman scattering (SERS), are less surface specific than SFG. ATR-FTIR detects signals from many layers, rather than the topmost layer on the surface. In addition, SERS requires special substrates to enhance the signal, which may not be ideal to study different surfaces and interfaces like biosurfaces.

SFG vibrational spectroscopy has been developed into a powerful analytical technique to examine molecular structures of surfaces and buried interfaces.[8–15] SFG is a second-order nonlinear optical spectroscopy, which can provide vibrational spectra of a surface or an interface with submonolayer sensitivity.[10–15] It does not require a high vacuum to operate; therefore it can be used to probe various surfaces/interfaces including liquid surfaces under ambient conditions. It can follow molecular-level chemical structural changes of surfaces and buried interfaces in situ and in real time. SFG spectrometers are more complicated compared to traditional Fourier transform infrared spectroscopy (FTIR) or Raman systems. Owing to the fast development of advanced lasers and nonlinear optical research, SFG equipment is becoming more mature, stable, and user-friendly. SFG research has grown substantially in recent years and numerous academic and industrial labs have been equipped with SFG systems (*see* **Theory of Infrared Spectroscopy**; **Infrared Spectroscopy: Introduction**; **Raman Spectroscopy: Introduction**; **Fourier Transform Raman Instrumentation**; **Raman Microscopy and Imaging**; **Raman Scattering, Fundamentals**; **Ultrafast Laser Technology and Spectroscopy**).

The aim of this article is to introduce the SFG technique and its applications to scientists in other research fields and to beginners in SFG studies who are not very familiar with this technique. Thus, only a brief introduction instead of an in-depth discussion of the SFG theory and technique is presented here. Many quantitative SFG data analysis methods and SFG technical details are omitted. Instead of thoroughly covering all the excellent SFG results from the many SFG research labs on a wide range of different research subjects, this article presents only applications of SFG with respect to several particular research directions to deliver a general idea to the readers about what SFG can examine and why the results obtained from such SFG studies are important and unique. More details can be found in the numerous excellent SFG review papers and original research articles.

The article is organized as follows: after this brief introduction, SFG theory and instrumentation are briefly discussed. Then SFG applications in studying liquid surface and interfaces of small molecules, polymer surfaces and interfaces, and interfacial biological molecules such as proteins and peptides, respectively, are presented. As stated, the purpose of this article is to introduce the SFG technique and its applications to the readers who do not know this technique well. It is hoped that this article will promote their interests in exploring the possibility of applying SFG spectroscopy to solve some of the questions in their research areas.

2 SUM FREQUENCY GENERATION THEORY AND INSTRUMENTATION

SFG spectroscopy provides vibrational spectra of molecules. SFG can elucidate surface/interfacial structures at the molecular level for a centrosymmetric material. FTIR and Raman scattering are the most widely used vibrational spectroscopic techniques. An SFG spectrum is similar to an FTIR or Raman spectrum, which plots the signal intensity as a function of infrared (IR) wavenumber, but an SFG spectrum is specifically from the surface functional groups in a centrosymmetric medium.

FTIR and Raman are linear spectroscopic techniques. FTIR is a one-photon process where an IR photon interacts with a molecule, and if its frequency is in resonance with a vibrational mode of the molecule and if the dipole moment changes during the vibration, the photon can be absorbed. A normal Raman process is a scattering process that involves two photons. The incoming photon can gain or lose energy when it interacts with the molecule. The outgoing photon will contain information about how much energy was gained or lost to the molecule, which is dependent on the vibrational energy levels of the molecule. The energy difference between the two photons matches the energy difference between vibrational states of the molecule. A vibrational mode is Raman active if the polarizability changes during the vibration.

As opposed to FTIR and Raman, SFG is a nonlinear process that involves three photons: two incoming photons and one outgoing photon. The outgoing photon is at the sum frequency of the two input photons. Figure 1 shows the energy-level diagrams of the IR, Raman, and SFG processes. Clearly an SFG process is a combination of an IR process and an anti-Stokes Raman scattering. In a typical SFG experiment using a frequency-scanning

Figure 1 Energy-level diagram of FTIR (a), Stokes and anti-Stokes Raman scattering (b1 and b2), and SFG (c).

Figure 2 SFG experimental geometry.

system, two input beams, a frequency-fixed visible light and a frequency-tunable infrared light, shine on a surface/interface (Figure 2) and the sum frequency signal beam is detected. The intensity of the sum frequency signal beam is plotted as a function of the input IR wavenumber. When the frequency of the input infrared beam matches a vibrational resonance of molecules on the surface, the SFG signal is enhanced. Only if a vibrational mode is both IR and Raman active can it be observed in SFG experiments.

Under the electric dipole approximation, SFG signal intensity is proportional to the square of second-order nonlinear susceptibility $\chi^{(2)}$ of the material under study. This $\chi^{(2)}$ is a polar tensor, so it will change sign under the inversion operation: $\chi^{(2)}(r) = -\chi^{(2)}(-r)$. However, for a material with inversion symmetry, nothing will be changed under the inversion operation: $\chi^{(2)}(r) = \chi^{(2)}(-r)$. Clearly the only possible solution for the above two equations is $\chi^{(2)} = 0$. Therefore, for materials with inversion symmetry the SFG process is forbidden. Many bulk materials do have inversion symmetry and thus they do not generate SFG signals. However, inversion symmetry is inherently broken at an interface. Here, $\chi^{(2)}$ does not need to be zero, and SFG signals can be detected. Owing to this selection rule, SFG is intrinsically surface specific and has been demonstrated to have a submonolayer surface sensitivity.[10–15]

As mentioned, ATR-FTIR and SERS have been widely applied to study surfaces. However, the surface sensitivity of ATR-FTIR is limited by the penetration depth of the IR light, which is on the order of hundreds of nanometers to a few micrometers. Thus, its surface sensitivity is not comparable to SFG. SERS requires a metal substrate and thus is not as flexible as SFG, which can be used to study many different kinds of surfaces and interfaces. In addition, SERS does not have the submonolayer sensitivity and surface specificity of SFG.

Two different kinds of SFG systems, either a broadband system or a frequency-scanning system, are typically used to collect SFG spectra.[16] A broadband system involves a femtosecond laser, which has a broad frequency spectrum. Therefore, many vibrational modes are excited simultaneously. The signal is typically spectrally spread over a charge-coupled device (CCD) camera and the signals from different vibrational modes are collected simultaneously. Further details have been reported in previous publications and will not be repeated here.[16]

The authors' research group has two frequency-scanning systems.[17] Each system is composed of the following components: a picosecond Nd:YAG laser, a harmonic unit with two KD*P crystals, an optical parametric generation (OPG)/optical parametric amplification (OPA) and difference frequency generation (DFG) system based on Lithium Triborate LiB_3O_5 (LBO) and $AgGaS_2$ crystals, and a detection system. The green visible input beam (532 nm) for an SFG experiment is generated by frequency doubling the fundamental output pulses of 20 ps pulse from the Nd:YAG laser. The IR beam can be tuned from ~1000 to 4300 cm^{-1}, generated from the OPG/OPA and DFG system. By replacing the $AgGaS_2$ crystal with a GaSe crystal, this range may be extended down to 650 cm^{-1}. The diameters of both the visible and IR beams at the surface are about 500 μm. The SFG signal from the surface is collected by a gated photomultiplier tube. The pulse energies of the IR and visible beams are around 100 and 200 μJ, respectively, depending on the samples used in the experiment. SFG spectra with different polarization combinations such as ssp (s-polarized output, s-polarized visible input, and p-polarized IR input), ppp, and sps can be used to deduce orientation information of surface functional groups.

SFG spectra are usually collected from optically flat surfaces, as shown in Figure 2. In the past, most SFG studies have focused on the C–H, N–H, or O–H stretching frequency regions because of experimental equipment limitations. Thus, the data analysis for these functional groups has been extensively studied. Recently, SFG signals in lower frequency regions have been collected and analyzed. In this article, structural information of proteins and peptides at interfaces according to their SFG amide I signals will be extensively discussed.

In addition to identification of various functional groups' presence on the surface from SFG signals (e.g. from characteristic peak centers), orientation information of such surface functional groups can be deduced from SFG spectra collected in different polarization combinations. Details regarding the orientation analysis of such surface functional groups using SFG have been extensively discussed in many previous publications[18–24] and will not be repeated here. The general idea is similar to a polarized FTIR or ATR-FTIR experiment. In a polarized FTIR experiment, when a different s- or p-polarized beam is used, the transition dipole of a vibrational mode of the molecule is projected onto different axes and such projections measured from which the orientation can be deduced. For SFG, the molecular

hyperpolarizability is projected onto the lab coordinate system when a certain polarization combination of input and output laser is used in the experiment. For example, according to the intensity ratio of different vibrational modes of a functional group in the same spectrum, or more frequently intensity ratio of the same peak in SFG spectra collected using different polarization combinations, orientational information can be determined. In addition, more details regarding such an orientation (e.g. orientation distribution) can also be deduced if the SFG absolute intensity can be calibrated.[24]

SFG results (e.g. the presence and orientation of various functional groups at an interface) can lead to a detailed understanding of the interfacial structures and molecular interactions at the interface. For example, if the orientation of certain domains in a protein at an interface using SFG can be determined, it might be possible to deduce the orientation of the entire protein molecule at the interface. Such information is important to understand how the protein interacts with a biomedical implant, how a membrane protein functions, or how an enzyme immobilized on a surface could be used as a biosensor. In the following, several examples to demonstrate various SFG applications will be introduced.

3 SUM FREQUENCY GENERATION APPLICATIONS

After the demonstration of the feasibility of collecting SFG vibrational spectra from interfacial molecules in 1987 by Shen et al.,[25] SFG has been developed into a powerful surface-sensitive analytical technique. It has been widely applied to study many important surfaces and interfaces, including many liquid surfaces and interfaces, which will be discussed in detail in the next section. Such research is still continuing and many papers have been published; thus, it is impossible to even cite all the representative and important papers. It is suggested that interested readers refer to the excellent reviews on this research (e.g. in the works of Eisenthal, Chen et al., Bain, Richmond, Shen, and Gopalakrishnan et al.[10–15]) and those original publications cited in these reviews.

After discussing the SFG studies on liquid surfaces and interfaces in the next section, relatively recent SFG results on polymers and biological molecules at interfaces will be discussed. Similarly, extensive excellent research has been performed in SFG studies on polymers and biological molecules and it is impossible to cover the entire research field. Instead, this paper will mostly focus on the research results from the Chen lab, with which the authors are most familiar.

3.1 Small Molecules at Interfaces Involving Liquids

3.1.1 Water/Air Interfaces

Compared to the surface analytical techniques that require high vacuum to operate, one of the most important advantages of SFG is that it can be used to study liquid surfaces and interfaces. Water is often considered to be one of the most important liquids, and it is important to understand water structures at surfaces and interfaces.

In 1993, Shen and his colleagues published their SFG studies on water surfaces in air.[9] They assigned three major peaks in the SFG spectrum collected in the O–H stretching frequency range (Figure 3). The $\sim$3700 cm^{-1} peak is contributed by free O–H groups (or dangling O–H bonds). Such O–H groups stick out from water into the air; otherwise, they would form hydrogen bonds with other water molecules. The two other peaks centered at $\sim$3200 and $\sim$3400 cm^{-1}, respectively, are hydrogen-bonded O–H stretching signals. Shen et al. referred to these two peaks as ''ice like'' (for $\sim$3200 cm^{-1}) and ''liquid like'' (for $\sim$3400 cm^{-1}) peaks, because they are close in positions with the stretch modes of the bonded O–H in bulk ice and water. However, the assignment for the 3200 cm^{-1} peak is still under debate.[15] From the spectral fitting, it was found that the $\sim$3700 cm^{-1} peak has a different phase compared to the hydrogen-bonded O–H signals ($\sim$3200 and $\sim$3400 cm^{-1}), showing that the hydrogen-bonded O–H groups are facing toward the water bulk. From the calibrated absolute signal intensity, it was deduced that more than 20% of the water molecules at the water/air interface have dangling O–H bonds.

It was found that the dangling O–H signal gradually decreased as methanol was mixed into the bulk water, and completely disappeared as the concentration reached 11% by volume.[26] It was determined that there is a 0.25 monolayer of O–H dangling bonds at the water/air

Figure 3 SFG spectrum collected from the pure water/vapor interface with ssp polarization combinations. Solid line is fitting result. (Reprinted figure with permission from Ref. 9. © 1993 by the American Physical Society.)

interface. When the dangling O–H bonds disappeared, the 3200 cm^{-1} peak dominates the spectrum, showing that the interfacial water molecules at the interface after introducing methanol are much more ordered compared to those at the water/air interface. SFG spectra were again collected from the water/air interface recently using different polarization combinations.[14] A new peak at ~3600 cm^{-1} was observed in the sps spectrum, which is assigned to the peak with bonded O–H stretch mode of surface water molecules with one bonded O–H and one dangling O–H. Temperature-dependent SFG signals of the water/vapor interfaces were collected and no strong temperate dependence was observed. The most noticeable change was an increase of the peak around 3400 cm^{-1} (disordered liquid-like peak).[14] This is different from some simulations that predict a strong temperature dependence for the surface structure of water.

3.1.2 Water/Hydrophobic Media Interfaces

Shen et al. also studied water structures at an interface between other hydrophobic surfaces and water, for example, the interface between a layer of octadecyltrichlorosilane (OTS) and water, and hexane and water. At the OTS/water interface,[26] free O–H signal has also been detected. The density of the O–H dangling bonds was measured and it was found that there is one dangling O–H bond in every four water molecules at the interface. This is similar to the water/air interface previously reported. Interestingly, comparing the SFG spectra collected from the OTS/water interface to the water/air interface, the 3200 cm^{-1} peak intensity from the OTS/water interface is much stronger. At a hydrophobic solid/water interface, the surface water molecules form a more ordered ice like structure because of the physical restriction involved in packing molecules against a solid. While at the hexane/water interface, the water spectrum was more similar to that collected from the water/air interface. In addition to the hydrophobic surfaces, water structure at the interface between a partially wettable surface and water was studied using SFG. In this case, the dangling water signal disappeared.[26]

To date, extensive research has been done on water surfaces and interfaces using SFG. Richmond et al. showed that water has a different structure at the CCl_4/water interface than at the water/air interface.[13] At the CCl_4/water interface, the hydrogen-bonded O–H species shift to higher frequencies, indicating significantly weaker hydrogen bonding at the CCl_4/water interface. These hydrogen-bonded water molecules at the CCl_4/water interface have weaker interactions with other water and CCl_4 molecules, leading to a frequency shift. However, the free O–H bonds peak at the CCl_4/water interface shift to 3660 cm^{-1} from the 3700 cm^{-1} at the water/air interface. Richmond's later research showed that this shift is the result of an attractive interaction between the dangling O–H bond and the surrounding CCl_4 molecules. Richmond also extensively investigated the effect of surfactant adsorption on water structure at interfaces. It was shown that the hydrogen bonding of water is highly sensitive to the presence of charged surfactants, with changes occurring in the water spectrum at trace concentrations in the aqueous solutions.[13]

3.1.3 Solution/Air Interfaces

Shultz et al. studied water surface structure at the sulfuric acid as well as sulfate solution surfaces. Sulfuric acid and sulfate aerosols are known to play a central role in atmospheric chemistry. Stratospheric sulfate aerosols are the dominant staging surfaces for reactions involved in ozone depletion. The determination of the distribution and orientation of water on the surface for 40–80 wt% ($0.1x$–$0.4x$) sulfuric acid would greatly help assess plausible mechanisms for stratospheric processes.[15] SFG spectra collected from the sulfuric acid solution in air indicated that the dangling water SFG signal was observed when a small amount of sulfuric acid was added to the water. However, when the solution contained $0.1x$ sulfuric acid, the free O–H signal was greatly reduced. No free OH signal was observed from the surface of solutions that contained a higher sulfuric concentration. The absence of this peak indicated a lack of dangling hydrogen atoms at the surface for stratospherically relevant concentrations. To determine whether the lower temperatures of the stratosphere result in greater partitioning of water to the surface, the SFG signal was examined as a function of temperature for a $0.2x$ solution.[27] Neither hydrogen-bonded water (discussed in the next section) nor free OH water was significantly altered for temperatures as low as 216 K. This showed that the surface structure was not altered at a lower temperature. Shultz et al. also studied surface structures of water at the water-sulfate solution surface. SFG spectra collected from the water/air interface were compared to those from the aqueous solutions of H_2SO_4, $LiHSO_4$, $CsHSO_4$, and $KHSO_4$ (keeping the anion concentration constant at $0.1x$). For H_2SO_4, the SFG intensity increased, especially for the 3150 cm^{-1} peak.

SFG signals from the sulfate solution surfaces showed a less dramatic but similar intensity increase. Schultz et al. believed that ''this intensity increase is attributed to an electric double layer that arises in the solution due to the differential distribution of anions and cations near the surface. Here the anion is larger and more polarizable than the cations. The hydration shell of the cations is therefore more strongly associated than that of the anion, limiting the approach of the cation toward the surface.

Similarly, the greater polarizability of the anions results in a lower enthalpic drive of anions away from the interface. As a result, the tail of the anion distribution extends further toward the interface than that of the cation. This differential distribution gives rise to a double layer just below the surface, and the negative pole of the double layer is directed at the surface.'' For smaller cations, for example H^+ and Li^+ studied here, along with HSO_4 create a stronger field, and therefore a greater enhancement of the 3150 cm^{-1} peak. For the larger cations, K^+ and Cs^+ at $0.01x$, it is easier for them to form ion pair with HSO_4^- and penetrate to the surface. Because of the presence of the ion pairs on the surface, the O–H dangling bonds are reduced, resulting in weaker free O–H signals.

Shen et al. also studied water structure at the sulfuric acid/water interface; details can be found in Raduge et al.[28] In addition to sulfate and bisulfate ions, water structure of halide ion solutions was investigated and compared to the theoretical simulations results. More details of the related research can be found in Gopalakrishnan et al.[15]

Cremer et al. studied how the presence of different Hofmeister anions in the solution altered the water structure next to a polymer.[29] Specifically, SFG spectra were collected from a solution surface with poly (*N*-isopropylacrylamide) (PNIPAM) on the surface (Figure 4). When different ions were added to the solution, the SFG signal from surface PNIPAM exhibited no change but the water signal changed substantially. The SFG signal contributed from O–H stretching was stronger for chaotropic anion solutions. The surface potential changes more for the chaotropic anion solution with PNIPAM on the surface – such results match SFG data quite well. Cremer et al. suggest that chaotropic anions segregate more easily to the solution surface to orient water to generate stronger SFG signals and induce bigger changes in surface potential. This is because ''adsorption behavior can be viewed as a partitioning of the anions between the interface and the bulk solution. The equilibrium constant and the bulk concentration dictate the distribution between these two states. For an anion to be adsorbed at the interface, it needs to undergo partial desolvation. The chaotropic anions have relatively low solvation free energies mostly because of their generally large size and high polarizability.[29] Therefore, a smaller desolvation penalty is paid compared with the kosmotropic anions.''

Ammonium is the only basic gas molecule that is important in environmental chemistry.[27] SFG has been applied to examine surface structures of ammonium aqueous solution. It was interesting to observe that the free O–H peak at ~3700 cm^{-1} actually contained two components at the ammonium solution/air interface (Figure 5). The peak at 3700 cm^{-1} became narrower when

Figure 4 Vibrational Sum Frequency Spectroscopy (VSFS) spectra show specific anion effects on PNIPAM adsorbed at the air/water interface. Each subphase contained 1 M of a given salt as indicated in the legend except for NaF and Na_2SO_4, which are measured with saturated solutions (~0.8 M for both salts). (b) The same experiments repeated with D_2O. The spectra are offset for clarity. (Reprinted with permission from *Journal of American Chemical Society*. © 2007 American Chemical Society.)

as little as $0.005x$ NH_3 was added and disappeared with a concentration of $0.04x$. A broader peak extending about 100 cm^{-1} beginning at 3680 cm^{-1} was observed until $0.33x$ NH_3 was added. When looking at the N–H stretching at ~3310 cm^{-1}, below $0.10x$, the ammonium resonance increased as the free O–H resonance decreases. The observation indicated that at low concentration ammonium titrated the free O–H bonds, simply docking to the dangling hydrogen through the ammonium long pair. When half of the free OH groups reacted with the ammonium, the decrease of the OH peak stopped until the ammonium concentration was doubled ($>0.20x$).

Figure 5 SFG spectra collected from ammonium solution surface: Free OH resonance of water (a) narrows and decreases with as little as $0.005x$ NH_3 (b) The broader resonance, shown for $0.10x$ NH_3 (c) persists to high concentration. 3.1.4 Water/Hydrophilic Solid Interfaces

Shen et al. studied the water structure at hydrophilic solid/water interfaces. For example, fused silica/water and crystalline quartz/water interfaces were investigated while varying the pH in water. Generally, the SFG spectra that were collected from the silica/water interface or quartz/water interface[26] were similar to those collected from the water surface in air, except there was no O–H dangling bonds signal. Both ice like and liquid like hydrogen-bonded OH signals were detected, indicating that the interfacial water molecules again form a partially ordered hydrogen-bonded network. Both the ~3200 and 3400 cm^{-1} peaks increase with pH, but the ice-like peak grew appreciably at high pH, suggesting a better polar-ordered network at high pH. To determine the absolute orientation of O–H groups at the quartz/water interface at different bulk pH of water, Shen et al. developed a phase-sensitive method from which it was feasible to deduce the O–H orientations.[14] The idea was to use the coherent property of the SFG technique to observe the interference between a bulk nonresonant SFG signal generated from crystalline quartz and the resonant SFG water signal. From such observed signal interference, it is feasible to deduce the phase information of SFG water signal; therefore, both real and imaginary components of the SFG signal from water can be deduced (Figure 6). It was found that the liquid like water maintained the same orientation when pH was varied, but the overall orientation of the ice like water flipped when the pH was increased. This technique of phase interference between a resonant signal of the analyte and a nonresonant background signal is a general method to measure the absolute orientation of interfacial molecules with SFG spectroscopy.

3.1.5 Charge Effect on Interfacial Water Structure

Richmond et al. studied the liquid/air interface of an aqueous solution with the surfactants sodium dodecyl sulfate (SDS), dodecylammonium chloride (dimethylammonium chloride, DAC), or a mixture of SDS and DAC (Figure 7).[13] SDS and DAC carry negative and positive charges, respectively. When the surfactants were added to water, they segregated to the surface, forming a negatively or positively charged surface, inducing strong water ordering near the surface. The SFG water signal became very strong owing to the strong ordering. When the neutral SDS and DAC mixture was added, no SFG water signal was observed.

Chen et al. collected SFG spectra from a protein solution surface in air (Figure 8). When the pH was varied, the SFG water signal had different intensities. When the pH was substantially higher or lower than the isoelectric point of the protein, the protein adsorbed at the solution/air interface carries negative or positive charges, which can orient the water molecules near the interface. This ordering generates much stronger SFG water signal than when the solution pH is close to the protein isoelectric point.[30] Clearly, interfacial charges greatly affect interfacial water ordering, and these changes can be detected using SFG.

3.2 Polymer Surfaces and Interfaces

The performance of many polymers is dominated by their surface properties, such as wettability, friction, lubricity, wearability, chemical reactivity, biological compatibility, biological activity, and permeability. These properties are widely used in many modern technological fields including biomaterials, microelectronics, display technology, coatings, and membranes for separations. Surface properties depend upon the chemical and physical details of the molecular structure at the polymer surface. In order to control surface properties by manipulating surface structure, we must have an extensive database of detailed correlations between properties and structures of the polymer surfaces.

SFG has been extensively applied to study molecular structures of surfaces and interfaces of a variety of polymer materials. In the following, after discussing

Figure 6 Real and imaginary SFG signals from water at quartz/water interface: An example of phase-sensitive SFG spectroscopic measurement for a quartz/water interface at pH of 6.5. (Reprinted figure with permission from Ostroverkhov, V., Waychunas, G. A., Shen, Y. R. *Phys. Rev. Lett.*, 2005, **94**, No. 046102. Copyright 2005, American Physical Society.)

how to quantify polymer surface structures using SFG, two particular SFG applications will be introduced: (i) polymer surfaces in water and (ii) structures of buried polymer interfaces related to polymer adhesion.

3.2.1 Quantitative Understanding of Polymer Surfaces

Polymers are large molecules and therefore polymer surface structures can be quite complicated. Before discussing how to quantify surface structures of polymer materials, a simpler surface, a surface of a self-assembled monolayer (SAM), for example, a methyl-terminated SAM on an Au surface will be discussed. Assuming the SAM surface has no defects, the surface is completely covered by terminal methyl groups. For an ideal sample, these methyl-terminated groups adopt the same orientation. Therefore, if the distribution of orientation angles of the methyl groups can be measured, it should be a delta distribution. If a surface is known to be completely covered by methyl groups, and if the orientation of all these methyl groups is deduced, the surface structure could be said to be understood quantitatively. Such quantitative structural information of a SAM surface can be obtained using SFG. SFG spectra collected from such a surface will show specific vibrational peaks for methyl groups, for example, 2875 cm^{-1} for symmetric C–H stretching, 2960 cm^{-1} for asymmetric stretching, and 2945 cm^{-1} for Fermi resonance. According to the intensity ratio of the signals detected in SFG spectra using different polarization combinations, the orientation of the methyl groups can be deduced. It is difficult to prepare a ''perfect'' SAM sample. The defects in SAM can change orientation

Figure 7 SFG spectra under ssp polarization conditions from the air–water interface of an aqueous solution of (a) a mixture of 0.02 mM dimethylammonium chloride (DAC) and 0.02 mM sodium dodecyl sulfate (SDS), (b) 0.05 mM SDS, and (c) 0.05 mM DAC. of some of the terminated methyl groups. The orientation distribution of the methyl groups cannot be described by a delta function then, but rather with a distribution with a certain width. If such an orientation distribution can be determined, then the surface with defects can be understood quantitatively.

A polymer surface may be more complicated and can have many different functional groups. The surface can also be quite disordered, meaning that the orientation distribution for each functional group can be very broad. A substantial number of different polymer surfaces have been investigated using SFG. It has been found that most polymer surfaces are dominated by one or two types of functional groups. If the surface-dominating functional groups can be identified, and if orientation distributions of these groups can be quantified, then the surface structure of these polymer materials can be quantified. Therefore, the quantification of polymer surface or interfacial structure can be realized by (i) identifying surface-dominating functional groups and (ii) deducing orientation distributions of such groups.

3.2.2 Sum Frequency Generation Studies on Polymer Surfaces in Water and Other Liquids

SFG has been applied to study surface structures of a variety of polymers in air. Examples of such polymers include polyethylene, polypropylene, various polymethacrylates, polystyrene (PS), poly (dimethyl siloxane) (PDMS), poly (ethylene glycol), poly (propylene glycol), polyimides, nylon, poly (ethylene terephthalate) (PET), and polyurethane.[11] SFG has also been used to study the surface structures of different polymer blends and copolymers. In addition, SFG has been applied to investigate structures of polymer surfaces in liquids and

Figure 8 SFG spectra of bovine serum albumin (BSA) solution/air interfaces with different solution pH values. (Reproduced with permission from Ref. 30. Copyright 2002, American Chemical Society.)

buried polymer interfaces, which will be the focus of the discussion here.

Polymer materials are widely used in various liquid environments. For example, polymeric biomaterials are routinely implanted into human bodies. Antibiofouling polymer coatings for marine vessels are used in ocean. Surfaces of polymer membranes for biological molecule separation are exposed to biological molecule solutions when in use. To ensure the desired performance of these polymers, it is important to characterize the polymer surface structures in aqueous environments.

SFG has been developed into a powerful technique to characterize surface-restructuring behavior in liquid environments. SFG spectra can be directly collected from the polymer/liquid interface, probing polymer/liquid interface in situ in real time with a submonolayer sensitivity and surface specificity.

3.2.2.1 Polymer Side Chain Changes in Water – Polymethacrylates SFG spectra from poly (*n*-butyl methacrylate) (PBMA) surface in air, in water, and after removing the sample from water were collected using different polarization combinations (Figure 9).[24] The SFG spectra

Figure 9 SFG spectra of PBMA in air and in water for (a) ssp and (b) sps polarization combinations. (Reproduced with permission from Ref. 24. Copyright 2002, American Chemical Society.)

collected from PBMA in air show different spectral features compared to those collected from PBMA in water, indicating that PBMA surface exhibits surface restructuring in water. The SFG spectra collected from the PBMA surface after removing it from the water and exposing to air again are similar to those collected before exposure to water, suggesting that the surface restructuring in water is reversible. The SFG spectra collected from PBMA in air and in water were both dominated by the signals contributed from methyl end groups of the ester chains. Comparing the symmetric and asymmetric methyl-stretching peak intensities in the spectra, it was determined that the methyl groups stand up more on the PBMA surface in air, and lie down more in water.

The SFG spectra collected using different polarization combinations can be used to deduce orientation

information of surface functional groups. The SFG polarized spectra measure components of second-order nonlinear optical susceptibility, which are related to different components of hyperpolarizability of the vibrational mode through $\langle \cos \theta \rangle$ and $\langle \cos^3 \theta \rangle$, where "$\langle\rangle$" means the average, and for methyl, θ is the angle between the principal axis of the methyl group and the surface normal. By measuring SFG spectra intensity in different polarization combinations, the ratio between $\langle \cos \theta \rangle$ and $\langle \cos^3 \theta \rangle$ can be determined. Assuming that every methyl has the same orientation – a delta orientation distribution – the orientation angle θ can be deduced. However, it is impossible to deduce $\langle \cos \theta \rangle$ and $\langle \cos^3 \theta \rangle$ individually with this ratio. In addition to collecting the SFG spectra using different polarization combinations, the absolute intensity can also be calibrated. With the help of absolute intensity, it is possible to deduce both $\langle \cos \theta \rangle$ and $\langle \cos^3 \theta \rangle$.

By assuming a Gaussian distribution for the orientation distribution of methyl groups, the orientation distributions of methyl groups on the PBMA surface in air and in water (Figure 10) can be determined. Figure 10 shows that methyl groups have a broader orientation distribution but a smaller average orientation angle in air. Methyl groups stand up more on the surface in air, and the surface is quite disordered (because methyl groups can have a broader range of orientation). In water, the orientation distribution is narrower, showing that the PBMA surface in water is more ordered. The average orientation angle of methyl on the PBMA surface in water is smaller, indicating that they lie down more toward the surface – perhaps due to the unfavorable interaction with water molecules.

To deduce the orientation distribution, it was assumed that the orientation distribution was a Gaussian function. To generalize this methodology for orientation distribution determination, a different trial function called the *maximum entropy function* was used.[24] Mathematically it has been proved that such a maximum entropy function leads to minimum bias under a limited amount of measurements. The orientation distribution deduced by using the maximum entropy function is similar to that of Gaussian function, showing that Gaussian function was a good approximation in this study.

Figure 10 Orientation distribution of methyl groups on the PBMA surface in air and in water. The angle in the x axis is the angle between the methyl principal axis and the surface normal. In air, the methyl groups have a small average angle, showing that they like to stand up on the surface with a broader distribution. In water, they tend to lie down with a narrower distribution (Reproduced with permission from Ref. 24. Copyright 2002, American Chemical Society.)

In addition to the PBMA, other polymethacrylates with different side chain lengths in water were studied. Some of them exhibit similar surface-restructuring behaviors as PBMA, including poly (ethyl methacrylate) (PEMA), poly (propyl methacrylate) (PPMA), and poly (hexal methacrylate) (PHMA).[31] Similar to PBMA, the orientation distributions of surface-dominating end methyl groups on PPMA, PHMA, and poly (octadecyl methacrylate) (PODMA) surfaces were deduced. The methyl end groups of the side chain tend to stand up with a broader distribution in air and lie down more with a narrower orientation distribution in water. They have very similar average orientation angle or orientation distribution in air, but small difference of the methyl group orientation on the PPMA, PBMA, and PHMA surfaces in water was observed (Figure 11). With the increase of the side chain length, the orientation angle increased with a narrower orientation distribution.[31]

The surface structural changes in water for PODMA were different. The average orientation angle and orientation distribution of surface-dominating methyl groups vary only slightly. It was found that PODMA was semicrystalline and therefore the surface was quite rigid and only small orientation changes of surface methyl groups were detected. The research in this section demonstrates that it was feasible to study surface-restructuring behaviors of polymeric materials in water quantitatively.[24,31]

3.2.2.2 Polymer Side Chain Changes in Water – Poly (dimethyl siloxane) PDMS surfaces also exhibit side chain orientation changes in water. PDMS, a good candidate for marine antibiofouling coating, has been extensively studied since the early 1970s.[32–34] However, understanding of its molecular surface structure in the aqueous environment in situ has not been achieved. Different types of PDMS materials can have different antibiofouling properties, because of their different surface structures. To elucidate the biofouling control and release properties of PDMS and their relation to molecular surface structures, SFG was used to examine molecular surface structures in air and surface-restructuring behavior in water of three different types of PDMS materials.[35] They were tetraethoxysilane-cured hydroxy-terminated poly(dimethyl siloxane) (TEOS-PDMS), platinum-cured vinyl-terminated poly(dimethyl

Figure 11 Gaussian orientation distributions for the side chain CH_3 groups on the surfaces of PPMA, PBMA, PHMA, and PODMA in (a) air and (b) in water (Reproduced with permission from Ref. 31. Copyright 2006, American Chemical Society.)

siloxane) (Pt-PDMS), and poly(dimethyl siloxane)-co-polystyrene (PDMS-*co*-PS) copolymer.

Using different polarization combinations of input and output light, SFG spectra were collected from the three PDMS surfaces in air as shown in Figure 12. All the SFG spectra were dominated by SFG signals contributed by the methyl groups on the PDMS side chains, showing that all surfaces are dominated by methyl groups. For Pt-PDMS, there are weak SFG signals due to the presence of $–Si–CH_2–CH_2$ moieties at cross-linking points on the surface. In the spectra collected from the PDMS-*co*-PS surface, there are several peaks above 3000 cm^{-1} that correspond to the aromatic C–H stretches from the phenyl group, indicating that on this surface, in addition to the methyl groups, phenyl groups also have some surface coverage. This research shows that small differences in surface structures of PDMS materials can be seen with SFG spectroscopy.

Surface-restructuring behaviors of these three PDMS materials in water were studied (Figure 13). For comparison, their surface changes in a hydrophobic fluorinated solvent, FC-75, was also studied. The SFG spectra collected from the three PDMS/water interfaces were very different from those of the PDMS/air interfaces. This would indicate that surface restructuring occurred in water. SFG data analysis indicated that when the hydrophobic PDMS surface contacted water the surface groups tended to reorganize by tilting more toward the surface to minimize interfacial free energy. At the PDMS-*co*-PS/water interface, the SFG signals due to methyl group stretches disappeared (Figure 13c) and only the signals due to the phenyl group stretches were visible. The disappearance of the methyl group stretches demonstrated that the methyl groups may reorganize differently at the PDMS-*co*-PS/water interface than at the other two

PDMS/water interfaces. The similarity in the SFG signals due to the phenyl group stretches at the PDMS-*co*-PS/air, water, and FC-75 interfaces indicated that the phenyl groups do not experience restructuring when the film contacted different solvents.

Figure 13 Measured and fitted SFG spectra (ssp) collected from three PDMS/water and PDMS/FC-75 interfaces: (a) TEOS-PDMS, (b) Pt-PDMS, and (c) PDMS-*co*-PS (Reproduced with permission from Ref. 35. Copyright 2004, American Chemical Society.)

Quantitatively, SFG results showed that the methyl groups at the Pt-PDMS/water interface tilt more toward the surface than those at the TEOS-PDMS/water interface. Unlike TEOS-PDMS or Pt-PDMS, the PDMS chains on the PDMS-*co*-PS surface are more mobile owing to the absence of cross-linked networks. Therefore, the molecular reorganization on the PDMS-*co*-PS/water interface became more complete and the interface was totally covered by the Si–O backbone, causing no SFG signals to be detected from the methyl group vibrational modes.

The SFG spectra collected from PDMS/FC-75 interfaces were more similar to the spectra from PDMS surfaces in air than those from PDMS/water interfaces. Detailed analysis of such SFG spectra showed clearly that in FC-75 methyl groups orient more toward the surface normal than those in air.

Through this study, the molecular-level chemical structures of several different PDMS surfaces in air and in liquid environments were studied using SFG. SFG can detect small differences in the surface structures of different PDMS surfaces, which cannot be differentiated by other techniques. Such molecular-level understanding of PDMS surface structures in various environments can provide detailed understanding of differences in antifouling properties of these PDMS materials. Previous research indicates that Pt-cured and alkoxysilane-cured PDMS have different stability in water and different antibiofouling performance.[36] Such differences should be caused by the different surface structures revealed by SFG. This research demonstrates that SFG is a powerful in situ technique to characterize surface structures of biofouling control/release polymer.

3.2.2.3 No Detectable Surface Restructuring in Water Other polymer surface-restructuring behaviors were also detected. The SFG spectra collected from the polymethylmethacrylate (PMMA) surface in water using different polarization combinations have similar spectral features to those collected in air, but weaker intensities.[37] Calculations indicated that the weaker intensities were due to the different refractive indices of water and air, rather than changes in the surface structures. PMMA surfaces were dominated by the ester methyl groups, and surface-dominating ester methyl groups did not exhibit detectable structural changes in water. This may be due to two reasons: (i) PMMA has a high glass transition temperature and therefore PMMA molecules including those on the surface are not very mobile and (ii) the ester methyl groups were more hydrophilic compared to the normal methyl groups. The ester methyl groups have a more favorable interaction with water than normal methyl groups.

3.2.2.4 Irreversible Polymer Surface Restructuring For methacrylates with longer side chains, such as poly (*n*-octyl methacrylate) (POMA) and poly (lauryl methacrylate) (PLMA), the SFG spectra collected in air indicated that their surfaces in air were still dominated by side chains.[31,37] However, substantial methylene signals can also be detected. Longer side chains have more gauche defects, generating stronger methylene signals. SFG signal was not detected from the polymer/water interface for POMA and PLMA, because the interfaces were totally disordered. The results showed that POMA and PLMA surfaces exhibit significant restructurings. The SFG spectra collected from the sample surface after removing the sample from water and exposing to air again did not completely recover. Both POMA and PLMA have very low glass transition temperatures (-20 and $-65\,^{\circ}C$ respectively), meaning the molecules can be very mobile and thus their surfaces exhibit substantial irreversible changes in water.

The SFG study of poly(ethyl acrylate) (PEA) showed that PEA had a similar surface-restructuring behavior as POMA and PLMA.[38] Like POMA and PLMA, PEA also has a very low glass transition temperature of $-21\,^{\circ}C$.

The SFG spectra were also collected from the surface of a PDMS sample that was not fully cured.[35] In air, the SFG spectra were similar to those collected from fully cured PDMS, indicating that the surface was dominated by $SiCH_3$ groups. No SFG signal was detected from the surface in water. The SFG spectra collected from the sample surface after removing the sample from water and exposing to air again did not completely recover. These observations differ from those of the fully cured PDMS materials, but were similar to those of POMA, PLMA, and PEA. It was suggested that this is due to the surface molecules of non fully cured PDMS being quite mobile. From the studies presented in this section, it is suggested that highly mobile molecules on the polymer surfaces in air can become totally disordered in water. After removing the polymer surface from water, the surface structure cannot recover.

3.2.2.5 Slow Surface Restructuring in Water For polymers discussed above, except for PMMA, which does not exhibit a detectable surface change in water, all other polymer surfaces exhibit restructuring behaviors immediately after contacting water. SFG research has shown that for some polymers surface restructuring can be a slow process. Somorjai et al. studied surface structural changes of a polyurethane with PDMS end groups in water.[39] This type of polymer has been used as a biomedical material. In air, because the PDMS silicone end groups are more hydrophobic, they cover the surface. When exposed to water, the more hydrophilic polyurethane backbone gradually segregates to the surface. SFG studies showed that after about 25 h the surface was dominated by the polyurethane backbone.

Chen et al. studied surface structural changes of a commercial polymer Sylgard 184 (unpublished results). As model PDMS surfaces that were discussed above, the Sylgard surface was also dominated by the $SiCH_3$ groups in air. Surface restructuring was detected after Sylgard surface was contacted with water. When the surface was removed from water and exposed to air again, the SFG spectra gradually recovered. The recovery process took tens of minutes.

3.2.2.6 Summary of Sum Frequency Generation Studies on Polymer Surfaces in Water Many important applications of polymers involve placing them in aqueous environments. Examples include biomedical polymer implants, marine antibiofouling coatings, polymer membrane for separation, and polymer coating for biosensors. Owing to the lack of applicable analytical techniques, some previous research studied polymer surface structures in air or in vacuum, and assumed that such surface structures are the same in water. It has been shown recently that SFG can probe molecular-level surface structures of polymers in situ in real time. SFG results indicated clearly that different polymer surfaces can exhibit varied restructuring behaviors. Some polymer surfaces showed reversible side chain orientation changes, others showed no surface change, and still others exhibited irreversible backbone changes. SFG results demonstrated that the assumption that polymer surface structures in air and in water are the same is not always a valid one.

Detailed surface-restructuring behaviors of various polymer surfaces in water revealed by SFG provide excellent experimental evidence for theoretical simulations. Chen et al. showed that molecular dynamics simulations of PS (using ethyl benzene as a PS model) surface in water (unpublished results) match SFG results quite well (unpublished results).

3.2.3 Sum Frequency Generation Studies on Buried Interfaces Involving Polymers to Understand Polymer Adhesion

3.2.3.1 Introduction Adhesion to polymer materials is important in many areas such as the automotive industry, aviation and aerospace, construction, electronics, industrial assembly and maintenance, paints and inks, and beauty and personal care.[40–43] For example, adhesives for polymers ensure the reliability and durability of coatings. Also, adhesives reduce the weight of a spacecraft by eliminating mechanical fasteners such as rivets. Similarly, from aircraft to automobiles to marine vessels, replacing rivets and bolts with adhesives will greatly reduce the vehicle weight and thus the amount of operation fuel, which is vital in energy conservation, environmental protection, and cost reduction. Adhesives also help distribute stresses over a wide area. Some other examples of the wide application of adhesion of polymer materials are in drug delivery, scar therapy, specialty cosmetic and hair replacement, and wound care products.[44] However, up to now the molecular-level understanding of adhesion mechanisms at polymer surfaces/interfaces has not been fully developed, which obstructs the systematic design of adhesives with the required performance.

For polymer adhesion applications, there is an increasing demand for silicone-based materials that can adhere to plastics, without surface priming or pretreatment.[40–42] Silicone elastomers are widely used because of their unique rheological properties, purity, and unsurpassed thermal stability and flexibility at a wide range of temperatures.[41] In particular, hydrosilylation- or addition-cured silicones offer advantages because of their clean cure chemistry and controllable and rapid cure kinetics. However, unlike condensation cure reactions, hydrosilylation-cured siloxanes are not naturally enriched

with polar, moisture-reactive groups and generally require the addition of adhesion-promoting additives.

Silane adhesion promoters are well suited for metals and other inorganic substrates that have reactive hydroxyl functional groups at their surfaces. Research also showed that alkoxysilane-based adhesion promoters could be quite effective in addition-curing silicones for imparting adhesion to some engineering thermoplastics, but the molecular mechanisms for such adhesion are not known.[45] Chen et al. studied the molecular structures of the silane molecules at buried polymer interfaces to understand the mechanisms of adhesion.

3.2.3.2 Molecular Structures of Silanes at Polymer/Silane Interface Chen et al. studied interactions at the interface between various polymers and different silanes. SFG spectra were directly collected from polymer/silane interfaces in situ.[46] The initially examined polymers include PMMA and PS. To avoid spectral confusion, deuterated PMMA (d-PMMA) and d-PS were used in the experiment. Chen et al. observed different structures of various silanes contacting PMMA or PS. The surfaces of both PMMA and PS are dominated by the ester methyl and phenyl groups, respectively.[17,47,48] The silanes that Chen et al. studied are *n*-octadecyltrichlorosilane (OTC, $CH_3(CH_2)_{17}SiCl_3$), and *n*-octadecyltrimethoxysilane (OTM, $CH_3(CH_2)_{17}Si(OCH_3)_3$).

The polymer/OTC and polymer/OTM interfacial SFG spectra did not change with time, indicating that these interfaces were stable. Different interfacial structures of silanes could be deduced by spectral analyses (Figure 14, see Chen et al.[46] for more details), and Chen et al. suggested that such structures were determined by the molecular interactions of the functional groups at these interfaces.[46] For example, the d-PMMA/OTC interface was dominated by the OTC methyl end groups as there were favorable interactions between these groups and the surface-dominating ester methyl groups of PMMA. At the PMMA/OTM interface, methoxy groups segregate to the interface that interacted more favorably with the PMMA ester methyl groups. At the PS/OTC interface, the OTC methylene backbones dominate the spectra. At the PS/OTM interface, both methoxy and methylene groups are detected. The restructuring of the ester methyl groups of PMMA and phenyl groups of PS at these different interfaces was also examined. This research clearly demonstrated that silane molecules adopt varied conformations at polymer/silane interfaces owing to different interfacial molecular interactions.[46]

3.2.3.3 Diffusion of Silanes into Polymers SFG was also applied to investigate structures of amino silane at the polymer/silane interface. Two amino silanes,

Figure 14 Schematic representations of different silane molecules oriented at the polymer/silane interfaces. The molecular segments (headgroup, backbone, and end group) of the silane molecules are represented as described by the legend. The boxes represent the bulk silane liquid. The SFG signals detected are primarily contributed from the molecular segments at the polymer/silane interfaces, that is, from those segments between the polymer substrate and the bulk. ●$-CH_3$, 〰$-CH_2-$backbone, • Si, ○ CL, o$-OCH_3$ (Reproduced with permission from Ref. 46. Copyright 2003, American Chemical Society.)

3-aminopropyltrimethoxysilane (ATM, $NH_2(CH_2)_3Si(OCH_3)_3$) and *N*-(2-aminoethyl)-3-aminopropyltrimethoxysilane (AATM, $NH_2(CH_2)_2NH(CH_2)_3Si(OCH_3)_3$) were studied.[46,49] The SFG spectra collected from the polymer/silane interfaces when either ATM or AATM were contacted at the PMMA or PS surfaces changed with time and finally decayed to zero. The signal disappearance at the PS interface is because ATM and AATM can dissolve PS. For PMMA, Chen et al. suggested that this phenomenon was due to strong interactions between the silane amino groups and the PMMA surfaces, resulting in the diffusion of the ATM and AATM molecules into the polymer. The diffusion of silane molecules was confirmed by a polymer bilayer experiment.[49] More specifically, the diffusion of AATM through the d-PMMA film was confirmed by SFG studies on the interface between AATM and a d-PMMA/PS two-polymer layer system. Initially the SFG signal from the PS layer was detected. However, after AATM diffused through the d-PMMA film, the PS film was dissolved by the silane, and thus the SFG signal from PS was lost. Chen et al. demonstrated that interdiffusion occurs much faster at the PMMA/ATM interface than at the PMMA/AATM interface. Using d-PMMA films of different thickness, Chen et al. showed that SFG could be used to monitor the chemical structures of moving interfaces during diffusion and to quantitatively deduce the diffusion coefficient (Figure 15). For AATM diffusion into PMMA, the diffusion coefficient was determined to be $(3.80 \pm 0.39) \times 10^{-13}\ cm^2\ s^{-1}$.[49]

SFG results also showed that (3-glycidoxypropyl)trimethoxysilane (γ-GPS, Figure 16) can diffuse through the d-PMMA film.[50] The diffusion of γ-GPS through the d-PMMA film was also confirmed by the polymer bilayer experiment. Similar experiments were carried out at the

Figure 15 (a) Dependence of the SFG signal intensity at 2840 and 2945 cm^{-1} collected from the d-PMMA/AATM interface as a function of the d-PMMA film thickness. The time taken by the AATM molecules to diffuse through the entire film increases with film thickness. The SFG signal can be detected during the diffusion process, showing that the moving interface is ordered. (b) Fitting of the diffusion time versus the d-PMMA thickness curve via a Fickian Model allows the diffusion coefficient to be deduced (Reproduced with permission from Ref. 49. Copyright 2004, American Chemical Society.)

interface between a silane adhesion–promoting mixture (SAPM) of γ-GPS and a methylvinylsiloxnanol (MVS, $n = 9$) (Figure 16) and the d-PMMA/PS two-polymer layer system. It was found that the diffusion time of the γ-GPS in the SAPM through the d-PMMA film was significantly longer.

3.2.3.4 Hydrogen Bond Formation at the Interface AATM and ATM did not diffuse into all polymer films. For example, stable SFG spectra were detected from PET/ATM interfaces (Figure 17).[51] The shift of the C=O stretching frequency at the PET/ATM interface compared to the PET/air interface indicated the formation of hydrogen bonds between the ester carbonyl groups on the polymer surface and the amino groups of ATM. Detailed analyses of the SFG signals in the C–H stretching region collected from the PET/ATM and PET/BTM interfaces revealed that the conformation of ATM molecules at the interface is different from that of n-butyltrimethoxysilane (BTM). Even though SFG signals of methoxy headgroups were observed from both PET/ATM and PET/BTM interfaces, using the phase analysis previously mentioned in this paper it was shown that the methoxy adopt different orientations at the PET/ATM and PET/BTM interfaces (Figure 18).[51]

3.2.3.5 Molecular Structures of Silane Mixture at Polymer/Silane Interface Chen et al. applied SFG to study interfaces between polymers such as PET and PS, and SAPM.[52] Adhesion tests at Dow Corning Corporation showed that a PDMS elastomer containing the mixture could effectively adhere to PET after curing at 150 °C. Incorporating the silane or the siloxane alone into the elastomer did not achieve good adhesion under the same cure conditions. At the PET/γ-GPS interface, weak methoxy signals were detected using SFG. It was found that the initial SFG signal collected from the PET/mixture interface was also weak; however, it grew with time indicating that the silane methoxy headgroups adopted a much different final orientation or orientational order at this interface than at the polymer/γ-GPS interface. This observation may be used to interpret the different adhesion behavior between the mixture and the single component. Also the SFG signals arising from the mixture were not the same at different polymer interfaces.[52]

3.2.3.6 Preliminary Results of Silanes at Silicone/Plastic Interface SFG spectra of the adhesion-promoting system at the buried silicone/PET interfaces were successfully detected.[53] When adhesion-promoting molecules such as γ-GPS or SAPM were incorporated into the silicone, the segregation of the silane methoxy headgroups were detected at the interface even when the bulk concentration of silane in the silicone is 1.5 wt%. Comparing SFG spectra from samples that were cured for different lengths of time suggests that there was interaction between the γ-GPS with the d_4-PET surface at the polymer/silicone elastomer interface. Diffusion of the silane into the polymer was discounted and the data suggest that both interfacial ordering and reactions may play roles in adhesion in this particular system. When other silanes were incorporated into the silicone, the methoxy headgroups were either not present or not ordered at the d_4-PET/elastomer interface.

Figure 16 Molecular formulas for (3-glycidoxypropyl)trimethoxysilane (γ-GPS) and methylvinylsiloxnanol (MVS, $n = 9$).

Figure 17 SFG spectra collected from the PET/air and PET/ATM interfaces in the C–H (a) and C=O (b) stretching regions. The shift of the C=O peak at the PET/ATM interface indicates the formation of interfacial hydrogen bonds (Reproduced with permission from Ref. 51. Copyright 2004, American Chemical Society.)

3.2.3.7 Summary From these SFG investigations on interfacial silanes, Chen et al. demonstrated that SFG is a powerful technique to elucidate polymer surface structures and polymer–silane interactions. It was observed that different silane structures at various interfaces were determined by the molecular interactions between the polymer surface functional groups and the functional groups that the silane were composed of, and certain silane molecules can diffuse into polymers. Chen et al. showed that hydrogen bonds formed between plastics and silanes, and mixing siloxane oligomers with silanes changed the silane structure at the plastic/silane interfaces.

3.3 Sum Frequency Generation Studies on Proteins and Peptides at Interfaces

3.3.1 Introduction

ATR-FTIR has been extensively applied to study the interfacial orientation of peptides and proteins through investigations on amide I signals. Amide I signals contain abundant information about protein backbone secondary structures. It has been shown that the amide I signal shifts frequency depending on secondary structure (*see* **Raman Spectroscopy in Analysis of Biomolecules**; **Vibrational Optical Activity of Pharmaceuticals and Biomolecules**; **Biomolecules Analysis: Introduction**; **Circular Dichroism in Analysis of Biomolecules**; **Two-dimensional Vibrational Correlation Spectroscopy in Biomedical Sciences**; **Infrared Spectroscopy of Biological Applications**).

Initially, most SFG studies on interfacial proteins were based on the C–H and N–H stretching ranges, which are mainly contributed by protein side chains, due to instrument limitations. More recently, SFG has been used to study interfacial protein backbone structure/conformation using amide I signals.

SFG has several distinct advantages over conventional ATR-FTIR. The intrinsic surface sensitivity of SFG ensures that SFG only probes proteins/peptides at the interface with no interference from signals contributed from proteins/peptides in the bulk environments. Unlike in FTIR, water-bending modes contribute almost no SFG signal; therefore, SFG amide I signals exhibit no water signal interference. It is necessary to subtract a very large background to obtain the FTIR spectra of interfacial proteins/peptides and this may introduce substantial errors. By collecting SFG spectra using different polarization combinations of these beams, much more structural information can be acquired. SFG is a coherent spectroscopy, and various vibrational modes can interact with each other. Thus, unlike FTIR, SFG spectral-fitting results can be tested experimentally.[54] Site-selective isotope labeling not only shifts the SFG peak of the site but also breaks the local symmetry to make the signal more prominent.

3.3.2 Advantages of Combining Multiple Vibrational Techniques in the Study

Different vibrational spectroscopic techniques measure different structural parameters.[55] For example, if the tilt angle of a structural element (e.g. an α-helix) is θ versus the surface normal, ATR-FTIR can determine the angle through measuring $\langle \cos^2 \theta \rangle$. For ATR-FTIR,

Figure 18 Schematics of (a) PET/ATM and (b) PET/BTM interfaces (Reproduced with permission from Ref. 51. Copyright 2004, American Chemical Society.)

this is the only measurement obtained and can only be used to determine one structural parameter. Therefore, to understand the orientation of the functional group, it must be assumed that all the groups at the interface adopt the same orientation or a δ-orientation distribution. In contrast, SFG can measure both $\langle \cos \theta \rangle$ and $\langle \cos^3 \theta \rangle$.[17,24] Thus, SFG can be used to deduce two different structural parameters, for example, orientation and distribution (assuming a Gaussian distribution function). However, if a chemical functional group adopts three different orientations (e.g. one protein has three α-helices, each with a different orientation in the membrane), then the two SFG measurements are not enough. By combining SFG and ATR-FTIR measurements, however, it should be possible to deduce such distributions. In the future, four-wave mixing (FWM) spectroscopy, which measures $\langle \cos^2 \theta \rangle$ and $\langle \cos^4 \theta \rangle$, could also be included in the study. FWM has the same selection rules as traditional Raman scattering, which are different from those of ATR-FTIR. Thus, FWM may measure $\langle \cos^2 \theta \rangle$ through different vibrational modes from ATR-FTIR. FWM may be used to confirm ATR-FTIR results. In addition, FWM can measure $\langle \cos^4 \theta \rangle$. More measurements can be used to deduce the orientation distribution more accurately, providing a more complete picture.

Figure 19 shows three cases for two α-helices in a protein: they have the same tilt angle, 30° versus the membrane normal, but different absolute orientations. ATR-FTIR can measure their tilt angle but cannot differentiate the three cases. SFG can differentiate these three cases: the top and bottom cases can generate strong SFG signals, while for the middle case no SFG signal can be observed owing to the inversion symmetry of the two helices. The top and bottom cases can be differentiated by collecting SFG spectra interfering with a nonresonant or resonant signal of a known phase, from which the absolute "up" and "down" orientations of the two helices can be deduced. From SFG alone, the orientation of the helices in the middle panel cannot be determined; the only information is that two helices have opposite orientation or they both lie down on the surface. If SFG measurements are combined with ATR-FTIR data, the orientation of the two helices in the middle panel can be determined: one tilts 30° up and the other 30° down. Therefore, the combined vibrational spectroscopic studies can lead to the determination of more structural information.

Figure 19 Combined SFG and ATR-FTIR studies can provide more detailed orientation.

When the protein crystal structure is known, it might be possible to deduce the membrane orientation of the entire protein from the orientation of the α-helical secondary structure, allowing a greater understanding of how membrane proteins function. When the crystal structure is not known, measuring orientations of secondary structure elements may help understand the overall structure. Assuming a protein contains several secondary structural motifs, if the orientation of each secondary structure can be measured, then the "general" or "rough" structure/conformation of this protein may be determined (Figure 20). More detailed structure can be achieved if structural information of connections (e.g. coils) between different secondary structural motifs can be further measured (e.g. by isotope labeling). As presented above, when a protein has multiple α-helices, it is difficult

Figure 20 The model protein has three α-helices and several β-sheets. If the orientations of such secondary structures can be deduced, the rough structure or conformation of the protein can be known. A more detailed structure can be understood if the structural information of connections between different secondary structures is achieved.

to measure their orientations using ATR-FTIR alone. The combined SFG, ATR-FTIR, and FWM approach would generate more experimental measurements to deduce more detailed orientation distributions and more complicated structural information.

3.3.3 *Maximum Entropy and Quantitative Analysis of Complicated Orientation Function*

From a mathematical point of view, the task of reconstructing a distribution from its measured orientational parameters (e.g. $\langle \cos^n \theta \rangle$) is known as an *inverse problem*. It has been shown that the maximum entropy function, $G_{\text{total}}(\theta) = \exp\left(\sum_{n=0}^{N} a_n \cos^n \theta\right)$, is the best choice for a limited number of measurements, in the sense that it uses the fewest assumptions about the system.

To demonstrate the power of using multiple measurements, a few examples using artificial distributions will be discussed next. The first example is to assume that $G_{\text{total}}(\theta)$ is a Gaussian distribution with $\theta_0 = 85^\circ$ and $\sigma = 30^\circ$. This could be the distribution of α-helical peptides at an interface with varied orientation of the α-helix. The second function is a sum of two Gaussian distributions with $\theta_1 = 35^\circ$, $\sigma_1 = 10^\circ$, $\theta_2 = 135^\circ$, and $\sigma_2 = 10^\circ$. Such a function could occur from the two coiled-coils in an interfacial fibrinogen molecule. The third example assumes $G_{\text{total}}(\theta)$ to be a combination of four δ functions. A possible physical meaning for the third function could be a monolayer of ordered molecules on a surface. In each molecule, there are four identical chemical groups (e.g. α-helices), which cannot be separated in the frequency domain, but they have different orientations versus the surface normal. The functions $G_{\text{total}}(\theta)$ assumed in the above three examples have the same average angle (85°) but have totally different orientation distributions. With one measurement (e.g. ATR-FTIR alone) only the average orientation angle can be measured, and the differences among these three cases cannot be observed. One measurement is far from adequate to differentiate the functions in these three examples. As mentioned above, using various vibrational techniques, it is possible to measure the following parameters: $\langle \cos \theta \rangle$, $\langle \cos^2 \theta \rangle$, $\langle \cos^3 \theta \rangle$, and $\langle \cos^4 \theta \rangle$.

The deduced functions for the above three hypothetical examples using different numbers of measurements are shown in Figure 21.[55] From this figure, the deduced functions from one measurement (e.g. ATR-FTIR measurement) do not match any of the three real distribution functions. However, with more independent parameters deduced from other experiments, the deduced function can be much closer to the real function. With more measurements, even the case of a complicated distribution with four peaks can be resolved. Certainly, if there is preliminary information regarding these four peaks, for example, if it is known that there are four peaks and each one is a delta function, then only four independent measurements are needed to deduce such a four-peak distribution. This can be the case for membrane proteins: they may more or less have the same orientation. Thus, it is reasonable to assume the distribution of each type of α-helical structure to be a δ distribution. In addition to the application of combined vibrational spectroscopy, isotope labeling and controlled perturbation of interfacial peptides/proteins can generate additional independent measurements, providing more orientational parameters to deduce complicated orientation distribution.

Figure 21 Assumed orientation distributions and deduced distributions with various numbers of hypothetical measurements. The y axis is the normalized population and x-axis is the orientation angle. (a) At least two measurements are needed to closely resemble the assumed Gaussian distribution; (b) at least four measurements are needed to closely resemble the assumed distribution of the two-Gaussian function; and (c) at least eight measurements are needed to closely resemble the assumed distribution of a four-δ function.

3.3.4 *Sum Frequency Generation Applications*

3.3.4.1 Feasibility of Detecting Sum Frequency Generation Amide I Signals Chen et al. demonstrated that it was feasible to collect SFG amide signals from protein molecules at interfaces in situ, allowing for the determination of backbone conformations of interfacial proteins using SFG.[56] To ensure that SFG can detect amide I signals from interfacial proteins, a near-total-reflection sample geometry was adopted (Figure 22). It was clear that the SFG amide I bands from the various proteins were quite different, indicating that secondary structures of various interfacial proteins were different.[56]

Figure 22 Schematic of the near-total-reflection SFG experimental geometry (Reproduced with permission from Ref. 56. Copyright 2003, American Chemical Society.)

3.3.4.2 Feasibility of Distinguishing Protein Secondary Structures Using Sum Frequency Generation Amide I Signals After demonstrating the feasibility of detecting SFG amide I signals, Chen et al. further showed that these signals can be used to distinguish various protein secondary structures[57] (*see* **Biomedical Spectroscopy: Introduction**).

α-helical Structure MSI-594 (Figure 23a and b) is an analog of the magainin 2 peptide. Figure 23(c) shows the SFG amide I signal collected from MSI-594 at the PS/solution interface. The main amide signal is centered at about 1650 cm^{-1}, showing that the α-helical structure of MSI-594 dominates.[57] The SFG spectrum can be fitted quite well using a single vibrational peak and a nonresonant background. For the fitted result, the peak center is at 1650 cm^{-1}. The SFG amide I signal collected from magainin 2 at the PS/magainin 2 solution interface is also centered at ~1650 cm^{-1}, indicating an α-helical structure (not shown). SFG amide signals from fibrinogen at various polymer/fibrinogen solution interfaces were detected.[58,59] The signals were also dominated by a peak centered at 1650 cm^{-1} owing to the contribution of two α-helical coiled-coils. In addition to the peak center, it was confirmed that this peak was dominated by α-helical contributions using SFG polarization analysis.[58,60]

β-sheet Structure Chen et al. demonstrated experimentally that SFG amide I signals could be detected from β-sheets.[57,61] Figure 24(b) shows the SFG amide I spectrum collected from tachyplesin I at the PS/solution interface and the fitting results. Tachyplesin I is known to have a β-sheet structure in aqueous environments and in membranes. The β-sheet structure of tachyplesin I is robust because such a structure is held by two disulfide bonds (Figure 24a). Therefore, Chen et al. believed that it should maintain a β-sheet structure at the PS/solution interface. The fitting results of Figure 24(b) showed three major peaks at 1645, 1664, and 1688 cm^{-1}, with several minor peaks at lower wavenumbers. Figure 24(c) displays the SFG spectrum collected from the PS/solution interface after the addition of dithiothreitol (DTT) to the solution. DTT reduced the two intramolecular disulfide bonds,[62] which are essential for tachyplesin I to maintain its β-sheet structure (Figure 24d). After the addition of DTT the 1688 cm^{-1} peak disappeared. As discussed in many published papers, amide I signals at 1688 and 1633 cm^{-1} can be ascribed to the B_1/B_3 and B_2 modes of antiparallel β-sheets, respectively.[63–65] The disappearance of the 1688 cm^{-1} peak upon the addition of DTT confirmed that this peak was generated by the β-sheet structure of tachyplesin I at the interface. Chen et al. further showed that SFG chiral spectra could be collected from interfacial tachyplesin, and such chiral

Figure 23 Diagram (a) and ribbon structure (b) of MSI594; (c) ssp SFG spectrum of MSI594 collected from the PS/MSI594 solution interface. Dots: experimental data; line: fitted spectrum. A nonresonant background is used in the fitting. The distorted spectral feature of the experimental data is caused by the nonresonant background.

Figure 24 (a) Diagram of tachyplesin I with s–s representing the intrastrand disulfide bonds and (b, c) SFG spectra and fitting results for 0.1mg/mL peptide adsorbed at the PS/solution interface with squares representing the actual data, the line through the data is the fitted spectrum and the curves under the data are the component peaks used to fit the spectra. (b, c) SFG spectra of tachyplesin I before and after contacting 10 mM DTT. (d) Schematic showing the loss of β-sheet structure following addition of DTT.

SFG signals were dominated by contributions from β-sheet structure.[61]

β-turns and Random Structure After the DTT treatment for tachyplesin, the SFG bands at 1645 and 1664 cm^{-1} remained. Following extensive study, Chen et al. suggested that these two peaks are due to turns, random structures, or a combination thereof.[63,64] SFG polarization analysis showed that their behaviors were very different from those of α-helical structures.

3.3.4.3 Determination of α-helical structure orientation SFG has been widely used to determine orientation of functional groups on surfaces and at interfaces using polarization analysis, which has mostly been focused on C–H groups such as methyl and phenyl groups.[18–20] Chen et al. recently extended this analysis to analyze SFG amide I signals using a group theory projection operator method to correlate SFG polarization measurements to α-helical structure orientation.[23] There are two SFG-active amide I bands for α-helical structure, A and E_1 modes. Their SFG measurables χ_{xyz} are related to their hyperpolarizability tensor elements β_{abc} through orientation as follows:

A mode :

$$\chi_{A,xxz} = \chi_{A,yyz} = 1/2N_s[(1+r)\langle\cos\theta\rangle - (1-r)\langle\cos^3\theta\rangle]\beta_{ccc}$$

$$\chi_{A,xzx} = \chi_{A,yzy} = \chi_{A,zxx} = \chi_{A,zyy} = 1/2N_s[(1-r)(\langle\cos\theta\rangle - \langle\cos^3\theta\rangle)]\beta_{ccc}$$

$$\chi_{A,zzz} = N_s[r\langle\cos\theta\rangle + (1-r)\langle\cos^3\theta\rangle]\beta_{ccc}$$

where $r = \beta_{aac}/\beta_{ccc}$

E_1 mode :

$$\chi_{E,xxz} = \chi_{E,yyz} = -N_s[(\langle\cos\theta\rangle - \langle\cos^3\theta\rangle)]\beta_{aca}$$

$$\chi_{E,xzx} = \chi_{E,yzy} = \chi_{E,zxx} = \chi_{E,zyy} = N_s(\langle\cos^3\theta\rangle)\beta_{aca}$$

$$\chi_{E,zzz} = 2N_s(\langle\cos\theta\rangle - \langle\cos^3\theta\rangle)\beta_{aca}$$

Here N_s is the surface density of α-helical repeat units. Since the SFG hyperpolarizability can be deduced from Raman and IR properties of the α-helical molecule, Chen et al. deduced the relations among different hyperpolarizability tensor elements to be $r = 0.54$ and $\beta_{aca} = 0.32\beta_{ccc}$ from experimental measurements of polarized Raman and IR.[66–69] The detailed analysis indicated that only two SFG measurables regarding orientation angle θ were independent: $\langle\cos\theta\rangle$ and $\langle\cos^3\theta\rangle$. Using different polarization combinations of the input and output laser beams, $\langle\cos\theta\rangle$ and $\langle\cos^3\theta\rangle$ could be deduced. If it is assumed that all the α-helical structures on the surface/interface adopt the same orientation, then $\langle\cos\theta\rangle$ and $\langle\cos^3\theta\rangle$ can be replaced by $\cos\theta$ and $\cos^3\theta$. Subsequently, the relationship between an SFG measurable and the orientation angle of the α-helix can be depicted.

3.3.4.4 Orientation Distribution of α-helical Coiled-coils in Fibrinogen at Interfaces: Combined Sum Frequency Generation and Attenuated Total Reflection Fourier Transform Infrared Spectroscopy Studies It might not be accurate to assume all the α-helical structures on a surface/interface to have the same orientation. In these cases, a distribution function should be employed. As discussed above, lacking preliminary information regarding such an orientation distribution, the maximum

Figure 25 (a) Schematic of the fibrinogen native structure; (b, c, e, and f) possible conformation of fibrinogen after adsorption to PS; (d) ssp SFG spectrum collected from fibrinogen molecules at the PS/solution interface (Reproduced with permission from Ref. 58. Copyright 2006, American Chemical Society.)

entropy function is the best trial function. Chen et al. studied orientation distribution of two α-helical coiled-coils of fibrinogen at the PS/fibrinogen solution interface.

Figure 25(a) shows a schematic of the native fibrinogen structure, which (roughly) possesses inversion symmetry. Therefore, if fibrinogen adopted the native structure after adsorption to a surface (Figure 25b, c), little or no SFG signal would be detected. Experimentally, very strong SFG signal was detected from the PS/fibrinogen solution interface (Figure 25d), showing that adsorbed fibrinogen molecules do not adopt the native structure. The SFG signal was dominated by a peak centered at 1650 cm^{-1}, which was mainly contributed by the α-helical coiled-coils. SFG polarization analysis confirmed that this 1650 cm^{-1} peak was dominated by contributions from α-helical structures. Chen et al. also used the NLOPredict software package from the Simpson group (Purdue University) to determine that fibrinogen domains other than coiled-coils did not contribute noticeable SFG α-helix signals. The observed strong coiled-coil SFG signal indicated that fibrinogen adopted a bent structure after adsorption (Figure 25e, f).

Figure 26(a) shows the bent fibrinogen structure and orientation distribution of coiled-coils deduced by assuming that all the fibrinogen molecules have the same orientation (a δ distribution), using the SFG intensity ratio measured with different polarization combinations of the input/output laser beams. Certainly such a distribution is unlikely because the polymer surface can be very complicated and thus induce different orientations or conformations of the fibrinogen molecules adsorbed. Figure 26(b,

Figure 26 (a) Orientation distribution of α-helical coiled-coils in fibrinogen after adsorption deduced by one SFG measurement and schematic of the fibrinogen bent structure; (b, c) orientation distributions of coiled-coils deduced by two (b) and three (c) measurements. (Reproduced with permission from Ref. 55. Copyright 2007, American Chemical Society.)

c) shows the orientation distributions of α-helical coiled-coils of fibrinogen adsorbed on PS deduced using two SFG measurements (assuming a Gaussian distribution) and using combined SFG and ATR-FTIR (maximum entropy distribution) method, respectively.[55] The two distributions are similar, showing that the Gaussian distribution was a good assumption. However, the two distributions are not identical, showing that a combination of vibrational spectroscopic techniques should deduce the real distribution more accurately. The calculated distribution was quite broad, indicating that adsorbed fibrinogen molecules can adopt a variety of orientations and conformations. Using only ATR-FTIR to study such orientation, as is currently common, would reveal only one measured orientation angle, 52°, which is far from the real picture where coiled-coils adopted a very broad orientation distribution. This research demonstrated the importance of using multiple independent measurements to study orientation of α-helices.

3.3.4.5 Studies of α-helical Structures in Lipid Bilayers Chen et al. also studied peptides in supported single lipid bilayers using SFG. It has been extensively shown that solid-supported lipid bilayers are valid models for cell membranes.[70] SFG was applied to investigate structures of such lipid bilayers.[71–73] For most of the research on supported lipid bilayers, glass, mica, and fused silica were used as solid substrates. Such surfaces can be negatively charged, which may induce interactions with peptides in the lipid bilayer, causing artifacts in the determination of peptide orientation in the bilayer. Chen et al. successfully constructed lipid bilayers on a variety of solid substrates such as SiO_2, CaF_2, and various polymers. It was found that the structure and stability of lipid bilayers on these substrates are identical to those on glass, mica, or fused silica.

Melittin in Membrane It has been shown that melittin adopts α-helical structure in the lipid bilayer by a variety of analytical methods, but the orientation of melittin in a lipid bilayer is still controversial.[70,74,75] Chen et al. first collected polarized ATR-FTIR spectra from melittin in a substrate-supported single lipid bilayer. This generates only one measured parameter: the intensity ratio of the s- and p-polarized ATR-FTIR absorbance. According to the ATR-FTIR results, the average orientation angle is 53.8° versus the surface normal.[76] The SFG spectra from melittin in a lipid bilayer (Figure 27) were then collected. Both spectra shown in Figure 27 can be exclusively fitted by a single peak centered at 1650 cm^{-1}, indicating α-helical structure. Using the SFG intensity ratio-orientation results, Chen et al. found that the SFG experimental data cannot be fitted using a δ-distribution or a Gaussian distribution (Figure 28).

Figure 27 SFG amide I spectra collected from melittin adsorbed onto a 1,2-Dipalmitoyl-*sn*-Glycero-3-[Phospho-*rac*-(1-glycerol)] (DPPG)-supported bilayer at ssp and ppp polarization combinations. A solution concentration of 0.78 mM is used (arbitrary unit). (Reproduced with permission from Ref. 76. Copyright 2007, American Chemical Society.)

Figure 28 $|\chi_{zzz}/\chi_{yyz}|$ ratio as a function of orientation angle, assuming a δ-distribution or Gaussian distribution function. Shaded area represents the actual experimental result. (Reproduced with permission from Ref. 76. Copyright 2007, American Chemical Society.)

If it is assumed that melittin can adopt two orientations, then combined SFG and ATR-FTIR results showed that the two orientation angles were $\theta_1 = 13°$ and $\theta_2 = 100°$ and coverages were $N_1 = 0.274$ and $N_2 = 0.726$, respectively (Figure 29a). These results were quite different from previous ATR-FTIR measurements, which suggested that these peptides were either perpendicular or parallel to the membrane surface. Chen et al. suggest that both orientations coexist.[76] Such a result should be

Figure 29 (a) Orientation distribution functions derived on the basis of a dual δ-distribution and (b) orientation distribution function derived on the basis of the maximum entropy theory (Reproduced with permission from Ref. 76. Copyright 2007, American Chemical Society.)

more reliable, because more measurements were used to derive the result.

Without assuming a two-δ distribution function as above, a similar result can be obtained by using a maximum entropy function as the trial orientation distribution. As mentioned, mathematically it can be shown that with limited measurements the maximum entropy function introduces the least bias. The deduced result using the maximum entropy trial function is shown in Figure 29(b). The distribution function in Figure 29(b) is similar to that shown in Figure 29(a) with two preferred orientations (Figure 30), but without initial assumptions.[76] This also suggests that for a protein with two (or even three) α-helical segments, the above method can be used to deduce their orientations.

G Protein Associated with Membrane Heterotrimeric guanine nucleotide-binding proteins (G proteins) are involved in numerous signal transduction pathways,[77,78]

Figure 30 Schematic of two orientations of melittin in the lipid bilayer (Reproduced with permission from Ref. 76. Copyright 2007, American Chemical Society.)

and relay the extracellular signals sensed by G protein–coupled receptors (GPCRs) to downstream effectors. A heterotrimeric G protein comprises three subunits, Gα, Gβ, and Gγ, with Gβ and Gγ forming a tightly associated dimer. Chen et al. studied the orientation of G$\beta\gamma$ in the lipid bilayer using SFG.[79] Two types of G$\beta\gamma$ unit were used in this research: one with

Figure 31 SFG ssp (weaker) and ppp (stronger) amide I spectra of interfacial G$\beta\gamma$ adsorbed onto a 1-Palmitoyl-2-Oleoyl-sn-Glycero-3-[Phospho-rac-(1-glycerol)] (POPG/POPG) bilayer. (a) 5 μL 10 mg mL^{-1} geranylgeranylated G$\beta\gamma$ was injected into the subphase and stronger SFG signals indicative of α-helix structure were observed. (b) 25 μL 10 mg mL^{-1} soluble form of G$\beta\gamma$ was brought into contact with the bilayer. Only relatively weak signals indicative of β-sheet were observed (Reproduced with permission from Ref. 79. Copyright 2007, American Chemical Society.)

Figure 32 Schematic of G$\beta\gamma$ adsorbed onto a POPG/POPG bilayer deduced from the SFG spectra shown in Figure 31: (a) geranylgeranylated G$\beta\gamma$ and (b) G$\beta\gamma$ with no geranylgeranyl group. (Reproduced with permission from Ref. 79. Copyright 2007, American Chemical Society.)

geranylgeranyl anchor group and the other without. The SFG spectra collected from these two types of G$\beta\gamma$ subunits were very different (Figure 31). The SFG spectra collected from the G$\beta\gamma$ unit with the geranylgeranyl group associated with the lipid bilayer had much stronger signal intensities, even when a much lower protein concentration was used. The SFG signal was dominated by a peak at around 1650 cm^{-1}, characteristic of contributions from α-helical components. Chen et al. suggested that the geranylgeranyl anchor group was inserted into the lipid bilayer and thus G$\beta\gamma$ units associated with the lipid bilayer adopted the same orientation, as shown in Figure 32(a). The β-sheet segments in this orientation did not contribute to SFG signals substantially because they have centrosymmetry, but the α-helices generated strong SFG signals centered at 1650 cm^{-1} because of the ordered orientation. The SFG intensities in the spectra collected from the G$\beta\gamma$ unit without the geranylgeranyl group associated with lipid bilayer were much weaker even though a much higher protein solution concentration was used. Chen et al. suggested that there were no specific interactions between the G$\beta\gamma$ and the bilayer without the presence of the geranylgeranyl anchor. In this case, the SFG signal is dominated by the contributions from the β-sheet structure (Figure 32b), centered around 1630 cm^{-1}. This indicates that it is necessary to have the anchor group on G$\beta\gamma$ to ensure the specific orientation associated with the membrane.

Figure 33 SFG spectra collected from G$\beta\gamma$ associated with different lipid bilayers: POPC:POPC; POPC:(POPC:POPG mixture); and POPC:POPG. The weaker signal in each panel is collected using ssp polarization combination and stronger one using ppp. Intensity ratios of ssp and ppp SFG signals are varied in different lipid bilayers, indicating that G$\beta\gamma$ adopts different orientations. The orientation of G$\beta\gamma$ in the POPC:POPC bilayer is shown in the upper left corner (Reproduced with permission from Ref. 79. Copyright 2007, American Chemical Society.)

The SFG spectra were also collected from $G\beta\gamma$ in lipid bilayers with different compositions (Figure 33): All three bilayers had an inner leaflet of 1-Palmitoyl-2-Oleoyl-*sn*-Glycero-3-Phosphocholine (POPC), while the outer leaflets that contacted $G\beta\gamma$ were varied as follows: POPG, POPG/POPC 1:1 mixture, and POPC. The SFG ppp/ssp spectral intensity ratios of $G\beta\gamma$ associated with various lipid bilayers were different, showing that $G\beta\gamma$ adopted different orientations owing to different lipid–protein interactions. The $G\beta\gamma$ orientation associated with the POPC:POPC bilayer was deduced and is shown in the upper left corner of Figure 33.

4 CONCLUSION

In conclusion, SFG vibrational spectroscopy is a powerful submonolayer-sensitive surface-specific analytical technique that provides a vibrational spectrum of surface functional groups on a centrosymmetric medium. SFG can provide both chemical specificity and orientation information. It has been applied to the study of a wide variety of systems, including complicated molecules such as polymers, proteins, peptides, and lipids at interfaces.

Terahertz spectroscopy has attracted great interest in recent years due to the development of improved terahertz radiation sources and terahertz radiation detectors as well as novel terahertz spectroscopy systems. This article discusses Fourier transform far-infrared spectroscopy, backward-wave oscillator terahertz spectroscopy, and time-domain terahertz spectroscopy. Terahertz spectroscopy is spectroscopy with electromagnetic radiation in the terahertz (THz) frequency range. THz radiation is invisible. The THz frequency range is located between microwaves and the infrared. THz spectroscopy measures the dielectric properties of liquid and solid as well as inorganic and organic materials in the THz frequency range. Furthermore, THz spectroscopy is a method for vibrational and rotational spectroscopy of gases.

Specifications and merits of Far-infrared Fourier transform spectroscopy, backward-wave oscillator terahertz spectroscopy, and time-domain terahertz spectroscopy for applications in analytical chemistry are compared. The frequency range, frequency resolution, and dynamic range of each method are discussed. Various measurement modalities such as transmission and reflection spectroscopy, phase-sensitive spectroscopy, and time-resolved THz spectroscopy are explained. The physical measurement principle of each method is discussed. The relationship between the measurement observed and the dielectric function of a material are presented for each method. Technical descriptions of the methods are provided. An overview on specific applications of THz spectroscopy is presented.

1 INTRODUCTION

Terahertz spectroscopy describes spectroscopy with electromagnetic radiation in the THz frequency range.[1] The THz frequency range is located between the microwave and the infrared frequency range (Figure 1).[2,3] Previously, this part of the electromagnetic wave spectrum was also referred to as the *submillimeter* or the *far-infrared* (FIR) frequency range. Correspondingly, submillimeter wave spectroscopy and FIR spectroscopy are synonyms of THz spectroscopy.[4–8] A frequency of 1 THz corresponds to a wavelength of 300 μm, a wavenumber of 33 cm^{-1}, or energy of 4.1 meV (Figure 2).

Terahertz spectroscopy measures the dielectric properties of materials. The method provides information on characteristic dynamical properties of materials in the gaseous, liquid, and solid state that occur on picoseconds to femtoseconds timescales. Terahertz spectroscopy is used to identify molecules in the gaseous state via characteristic rotational and vibrational absorption lines. Materials that form periodic crystals can be identified by THz spectroscopy through their phonon-absorption bands in the THz frequency range. Liquids and disordered solid materials generally show broad absorption bands at THz frequencies. However, in this case, it is possible to distinguish between different materials using THz spectroscopy based on dielectric contrast.

Terahertz spectroscopy has a long and successful tradition.[9] The first observation of the rotation spectrum of HCL was published in 1925. Since then, the development of THz spectroscopy and its applications in analytical chemistry has been driven by improvements in THz radiation sources, THz radiation detectors, and THz spectrometers. Accordingly, different approaches to THz spectroscopy have been developed. Earlier, THz spectroscopy was performed with grating spectrometers.[10] This approach was followed by two-beam interferometric spectrometers.[11–15] These types of THz spectrometers rely on thermal radiation sources and THz detectors such as Golay cells, bolometers, photoconductors, or pyroelectric devices.[16] The invention of coherent THz radiation sources such as backward-wave oscillators (BWOs), FIR molecular gas lasers, and THz quantum cascade lasers resulted in the development of scanning frequency THz spectrometers.[17–20] A recent development in THz spectroscopy is time-domain (TD) THz spectroscopy.[1] This method employs very short

pulses ($\leq 10^{-12}$ s) for broadband spectroscopy in the 0.1–3 THz frequency range. The THz radiation pulses are generated using femtosecond near-infrared (NIR) laser pulses incident on semiconductors or nonlinear optical crystals.[21,22] The THz radiation pulses are detected using photoconducting antennas or electrooptic sampling.[23–26] Time-domain THz spectroscopy measures the complex dielectric function of a material with high dynamic range.[27]

All methods of THz spectroscopy discussed so far have in common that the material to be analyzed is illuminated with THz radiation from a THz radiation source. Another approach to THz spectroscopy is the detection and spectral analysis of THz radiation naturally emitted by a material. This type of THz spectroscopy is used as an experimental method in astronomy. It is performed with THz heterodyne spectrometers.[28]

Today, commercially available THz spectrometers for analytical chemistry are far-infrared Fourier transform spectrometers (FIR-FTS), BWO THz spectrometers, and TD THz spectrometers. The specifications and performance of these three methods are discussed in the subsequent text.

2 SPECIFICATIONS AND PERFORMANCE OF DIFFERENT METHODS OF THz SPECTROSCOPY

2.1 Performance

In analytical chemistry, the important specifications for THz spectroscopy are the frequency range, the frequency resolution, and the dynamic range of measurement. The dynamic range is defined as the ratio of the largest to the smallest change in transmission (or reflection) that can be detected by a measurement, and is generally a function of frequency. The values of the dynamic range quoted in this article refer to maximum performance. Also, this article specifies the performance of commercially available THz spectrometers.

The performances of FIR-FTS, BWO THz spectrometers, and TD THz spectrometers differ by frequency range, frequency resolution, dynamic range, and absolute THz radiation power (Table 1). The frequency ranges of the different methods are also illustrated in Figure 3. A BWO THz spectrometer covers the 0.035–1.4 THz frequency range, whereas that of a TD THz spectrometer extends from 0.030 to 3 THz. The frequency range of operation of a BWO THz spectrometer strongly overlaps with that of a TD THz spectrometer The FIR-FTS spectrometer starts operating at 0.3 THz. The frequency range of this type of instrumentation extends into the infrared part of the electromagnetic spectrum.

The difference in performance between BWO THz spectroscopy and TD THz spectroscopy are frequency

Table 1 Performance of commercially available THz spectrometers

Spectrometer	Frequency range (THz)	Frequency resolution (MHz)	Dynamic range of THz power measurements	Absolute THz power (W)
BWO THz	0.035–1.4	1–10	$10^5 : 1$	10^{-3}
TD THz	0.02–3	1000–10000	$10^8 : 1$	10^{-6}
FIR-FTS	>0.3	1000–10000	300 : 1	10^{-9}

Figure 3 Frequency range of operation of time-domain (TD) spectroscopy, backward-wave oscillator (BWO) spectroscopy, and far-infrared Fourier transform (FIR-FTS) spectroscopy.

resolution and dynamic range. BWO THz spectroscopy allows measurements with 1–10 MHz resolution, whereas the frequency resolution of TD THz spectroscopy is restricted to 1–10 GHz. The dynamic range of TD THz spectroscopy is $10^8 : 1$, whereas that of a BWO spectrometer is $10^5 : 1$.

The frequency range of FIR-FTS starts at 0.3 THz and extends into the midinfrared and NIR (30–300 THz) range. The frequency resolution of FIR-FTS is 1–10 GHz. It is similar to the frequency resolution of TD THz spectroscopy but is lower than that of BWO THz spectroscopy. The dynamic range of FIR-FTS is much lower than that of BWO THz spectroscopy and TD THz spectroscopy.[29]

In summary, the frequency range of BWO THz spectroscopy and TD THz spectroscopy is very similar. BWO THz spectroscopy is the method of choice for analytical chemistry if spectroscopy with megahertz frequency resolution is desired. TD THz spectroscopy is selected for a spectroscopic measurement if it is necessary to measure very small changes in transmission (or reflection) but megahertz frequency resolution is not needed. The dynamic range of a FIR-FTS below a few THz is low compared with that of BWO THz spectroscopy and TD THz spectroscopy. The strength of an FIR-FTS is that it permits broadband spectroscopy from the THz frequency range into the infrared.

2.2 Merits

All three approaches to THz spectroscopy discussed in this article (Table 2) permit measurements in transmission and reflection geometry. BWO THz spectroscopy and TD THz spectroscopy are phase-sensitive methods of spectroscopy. FIR-FTS is a non-phase sensitive measurement method. Phase-sensitive spectroscopy allows the measurement of the real and imaginary part of the dielectric function of a material. Non-phase sensitive spectroscopy measures only the absorption coefficient of a material. TD THz spectroscopy also allows time-resolved spectroscopy with picoseconds to femtoseconds resolution.

In THz transmission spectroscopy, the THz radiation is incident perpendicular onto the surface of the sample (Figure 4a). Part of the THz radiation beam is reflected from the sample surface and part of it is transmitted through the sample. In THz transmission spectroscopy, the THz radiation transmitted through the sample is recorded by the detector. In THz reflection spectroscopy, the angle of incidence onto the sample is off from the sample surface normal. The THz radiation beam

Table 2 Merits of different methods of THz spectroscopy

Measurement	BWO THz	TD THz	FIR-FTS

Physical observables	Transmission Reflection	Transmissivity Reflectivity	Transmissivity Reflectivity
Principles	Frequency tuning Multiple-beam interference of continuous-wave monochromatic THz radiation	Frequency multiplexing Single beam of broadband THz radiation pulse Demultiplexing by Fourier transformation from time-to-frequency domain Time-resolved spectroscopy with femto-to-picosecond resolution (THz- emission spectroscopy, Optical pump/THz probe spectroscopy)	Frequency multiplexing Two-beam interference of continuous-wave broadband THz radiation Demultiplexing by Fourier transformation from space-to-frequency domain

Figure 4 Terahertz spectroscopy measurement modalities. (a) THz spectroscopy in transmission configuration. (b) THz spectroscopy in reflection configuration.

reflected off the sample surface is recorded by the detector (Figure 4b).

The transmissivity $T = I_t/I_0$ or reflectivity $R = I_r/I_0$ of the sample are defined as the ratio of the transmitted I_t or reflected intensity I_r and the intensity of the incident THz radiation I_0. The transmission or reflection coefficient $t = E_t/E_0$ and $r = E_r/E_0$ are the ratio of the transmitted electric field E_t or reflected electric field E_r to the incident THz electric field E_0.

TD THz spectroscopy measures the transmission t (or reflection r) of a sample. The transmission t (or reflection r) of the sample is determined by the complex index of refraction $n = n_0 + ik_0$ of the sample material. Here, n_0 is the index of refraction and k_0 is the attenuation coefficient. The relationships between transmission t (or reflection r) and the complex index of refraction are described by Fresnel's equations.[30]

$$t(\omega) = \frac{4n \exp\left[-\mathrm{i}\frac{\omega}{c}nd\right]}{(n+1)^2\left(1 - \left(\frac{n-1}{n+1}\right)^2 \exp\left[-2\mathrm{i}\frac{\omega}{c}nd\right]\right)} \quad (1)$$

$$r_p(\Theta, n(\omega)) = -\frac{n^2(\omega)\cos\Theta - \sqrt{n^2(\omega) - \sin^2\Theta}}{n^2(\omega)\cos\Theta + \sqrt{n^2(\omega) - \sin^2\Theta}} \quad (2)$$

$$r_s(\Theta, n(\omega)) = -\frac{\cos\Theta - \sqrt{n^2(\omega) - \sin^2\Theta}}{\cos\Theta + \sqrt{n^2(\omega) - \sin^2\Theta}} \quad (3)$$

In Equations (1)–(3), d is the sample thickness, $c = 3 \times 10^8\,\mathrm{m\,s^{-1}}$ is the velocity of light, $\omega = 2\pi f$ is the angular frequency with f being the frequency, and θ is the angle of incidence. Furthermore, r_p and r_s are the reflections in the case of the incident THz electric field being polarized parallel (p) or perpendicular (s) to the plane of incidence. These equations apply for a homogenous sample with parallel front and back surfaces, which are embedded in air. Similar equations have been developed for samples consisting of multiple layers of different materials and a thin conducting layer on a transparent substrate.[30] The complex index of refraction n of the sample is obtained from the measured transmission t and reflection r by numerically solving Equations (1)–(3). Computational routines have been developed for this purpose.[31] The complex index of refraction is related to the complex dielectric function $\varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega)$ and the complex conductivity $\sigma(\omega) = \sigma_1(\omega) + i\sigma_2(\omega)$ by the following relationships $\varepsilon = n^2$, $\varepsilon_1 = {n_0}^2 - {k_0}^2$, $\varepsilon_2 = 2n_0k_0$, and $\sigma = i\omega\varepsilon\varepsilon_0$. The power absorption coefficient α of a material as defined by the Bouguer–Lambert law of transmission $I_t \propto I_0 \exp(-\alpha d)$ is calculated using k_0 and $\alpha = 4\pi k_0/\lambda$, where $\lambda = c/f$ is the wavelength of the THz radiation. TD THz spectroscopy is phase sensitive because a single transmission or reflection measurement provides both the real and imaginary part of the complex index of refraction.

It is possible to perform time-resolved THz spectroscopy with femtoseconds to picoseconds temporal resolution using TD THz spectroscopy.[27] The THz radiation pulses in a TD THz spectrometer are generated using a femtosecond NIR laser pulse. The femtosecond NIR laser beam is divided by a beam splitter on a pump beam, which excites the THz radiation pulse, and a probe beam that gates the THz detector. The temporal profile of the THz radiation pulse transmitted through

Figure 5 Schematic of experimental arrangements of time-domain THz spectroscopy and optical pump/THz probe spectroscopy.

(or reflected) from the sample is recorded by delaying the probe beam relative to the pump beam by an optical delay line. In optical pump/THz probe spectroscopy, the femtosecond NIR laser beam is divided into three beams: the pump beam for THz pulse generation, the probe beam for gating of the THz detector, and the optical pump beam. The optical pump beam is also incident on the sample surface and is aligned such that the optical beam focus and THz beam focus overlap. Absorption of the femtosecond NIR laser pulse by the sample drives the sample out of equilibrium. The return of the sample to equilibrium is probed by the THz radiation beam by delaying it relative to the femtosecond NIR pulse. This results in time-resolved THz spectroscopy with femtosecond-to-picosecond resolution and provides insight into the dynamic dielectric properties of a material (Figure 5).

BWO THz spectroscopy measures the transmissivity T or reflectivity R of the sample under investigation.[17,32] The principle of BWO THz spectroscopy is multiple-beam interference. This is achieved because of multiple reflections of the continuous-wave THz radiation beam within the plane–parallel front and back surfaces of the sample. For transparent samples, the multiple-beam interference results in transmissivity and reflectivity of the sample changing periodically as a function of the THz frequency. The period of the oscillations is directly related to the index of refraction n_0 of the material by $m\lambda/2 = n_0 d$, where λ is the THz radiation wavelength, m is the number of interference maxima, and d is the sample thickness (Figure 6). The absorption of the material determines the minima in the interference pattern. Low absorption is indicated by low minima. The general relationship between transmissivity T or reflectivity R of the sample and the index of refraction n_0 and attenuation coefficient k_0 is described by Equations (4), (5), and (6).[17]

$$T = \exp\left(-\frac{4\pi k_0 d}{\lambda}\right) \frac{(1-R)^2 + 4R\sin^2\psi}{\left(1 - R\exp\left(-\frac{4\pi k_0 d}{\lambda}\right)\right)^2 + 4R\exp\left(-\frac{4\pi k_0 d}{\lambda}\right)\sin^2\left(\frac{2\pi n_0 d}{\lambda} + \psi\right)} \tag{4}$$

$$R = \frac{(n_0 - 1)^2 + {k_0}^2}{(n_0 + 1)^2 + {k_0}^2} \tag{5}$$

$$\psi = \arctan\left(\frac{2k_0}{n_0^2 + {k_0}^2 - 1}\right) \tag{6}$$

The index of refraction n_0 and attenuation coefficient k_0 of the sample are obtained by fitting Equations (4)–(6) to the measured transmissivity.

In the case of strong absorption of the sample, the interference maxima and minima are less pronounced (Figure 7). In this situation, it is necessary to measure, in addition to the transmissivity T, the phase delay Φ of the THz radiation transmitted through the sample.

$$\Phi = \frac{2\pi nd}{\lambda} - \arctan\frac{k_0(n_0^2 + {k_0}^2 - 1)}{({k_0}^2 + n_0^2)(2 + n_0)n_0} + \arctan\frac{R\exp\left(-\frac{4\pi k_0 d}{\lambda}\right)\sin\left(2\left(\frac{2\pi nd}{\lambda} + \psi\right)\right)}{1 - R\exp\left(-\frac{4\pi k_0 d}{\lambda}\right)\cos\left(2\left(\frac{2\pi nd}{\lambda} + \psi\right)\right)} \tag{7}$$

The index of refraction n_0 and attenuation coefficient k_0 are obtained by fitting Equations (4)–(7) to the measurements of T and Φ.

BWO THz spectroscopy and TD THz spectroscopy are both phase-sensitive methods of THz spectroscopy. They measure the real and imaginary part of the dielectric function of the sample. Because TD THz spectroscopy measures transmission (or reflection), the complex index of refraction of a material is obtained

Figure 6 Transmissivity of a plane–parallel gallium arsenide (GaAs) crystal measured with a BWO THz spectrometer.

Figure 7 Transmissivity of a plane–parallel calcite ($CaCO_3$) crystal measured with a BWO THz spectrometer.

from two measurements for transparent as well as strongly absorbing materials. In contrast, BWO THz spectroscopy, which measures transmissivity (or reflectivity), requires four measurements to obtain the complex index of refraction for strongly absorbing materials. Moreover, BWO THz spectroscopy measures only the static dielectric properties of a material. An advantage of a continuous-wave BWO THz spectrometer is that this instrument provides high frequency resolution and high dynamic range simultaneously. For a TD THz spectrometer, the dynamic range of the measurement decreases drastically with subgigahertz frequency resolution. The dynamic range and the frequency resolution are linked in TD THz spectroscopy due to the pulsed nature of the radiation and the TD measurement approach.

FIR-FTS also measures the transmissivity (or reflectivity) of a sample under investigation.[11,12,14,15] The principle of FIR-FTS is two-beam interference of broadband THz radiation (Figure 8). Generally, FIR-FTS is performed with a Michelson interferometer and relies on Fourier transformation between the space and frequency domain. It measures the Fourier transform $I(s)$ of the transmission (or reflection) spectrum of a sample as a function of the spatial delay s between two interfering beams, as described in Equation (8). In this equation,

Figure 8 Schematic of a far-infrared Fourier transform spectrometer.

$k = 2\pi/\lambda$ is the wavenumber, I is the total intensity of the broadband THz radiation source, and $I(k)$ is the intensity of the THz radiation in the wavenumber interval $\mathrm{d}k$, as described in Equation (9). The actual transmission (or reflection) spectrum of the sample is obtained by numerically calculating the inverse Fourier transform $I(k)$ of the measurement $I(s)$. The relationship between spectrum $I(k)$ and measured Fourier transform $I(s)$ is described in Equation (10).[33]

$$I(s) = \frac{1}{2}I + \frac{1}{4}\int_{-\infty}^{\infty} I(k)\exp(\mathrm{i}ks)\,\mathrm{d}k \tag{8}$$

$$I = \frac{1}{2}\int_{-\infty}^{\infty} I(k)\,\mathrm{d}k \tag{9}$$

$$I(k) = \frac{2}{\pi}\int_{-\infty}^{\infty}\left\{I(s) - \frac{1}{2}I\right\}\exp(-\mathrm{i}ks) \tag{10}$$

The transmission (or reflection) spectrum measured by FIR-FTS provides information on the absorption frequencies, the relative strength of an absorption line, and the linewidth of the absorption. The absorption coefficient α of the material is obtained by using the Bouguer–Lambert law $I_t \propto I_0\exp(-\alpha d)$ and measuring the transmission spectrum of two samples with different thickness d. FIR-FTS measures the static absorption coefficient of a material. Since FIR-FTS is non-phase sensitive, it does not provide information on the index of refraction of the material. In order to obtain the index of refraction of a material by FIR-FTS, it is necessary to measure the transmission and reflection spectrum of a sample. Another approach for obtaining the index of refraction is performing a Kramers–Kronig analysis of the measured absorption coefficient. However, the accuracy of this computational method requires measurements

of the absorption coefficient over a wide range of frequencies.

The advantage of TD THz and BWO THz spectroscopy over FIR-FTS is the capability of phase-sensitive measurements that allows the direct determination of the index of refraction and attenuation coefficient of materials in the 0.02–3 THz frequency range. The advantage of FIR-FTS is the rapid determination of absorption lines, their relative strength, and linewidth over a wide frequency range of 0.3–300 THz.

TD THz spectroscopy is performed in the time-domain and FIR-FTS spectroscopy is performed in the space domain. Both methods rely on frequency multiplexing, which describes that all frequencies represented in the broadband THz radiation source are incident on the sample simultaneously. For both methods, frequency demultiplexing is performed by Fourier transformation of the measurement to the frequency domain. BWO THz spectroscopy is performed in the frequency domain. The spectrum is recorded by continuously changing the emission frequency of the BWO THz radiation source. The advantage of a BWO-tunable THz radiation source in comparison to a FIR-FTS is that frequencies less than 1 THz are beyond the useful measurement range of most FIR-FTS. The much higher brightness of the BWO THz radiation source results in a much larger signal-to-noise ratio at frequencies below 1.4 THz.

3 TECHNICAL DESCRIPTIONS

3.1 Far-infrared Fourier Transform Spectrometer

Fourier transform spectroscopy is a method used for spectroscopies in the FIR (THz) and ultraviolet frequency range.[3] The basic components of a Fourier transform spectrometer are a broadband THz radiation source, a two-beam (Michelson) interferometer, and a broadband detector (Figure 8). The components are selected according to the frequency range of operation. In the FIR (0.3–20 THz), the radiation source of choice is a globar. Sensitive detectors for FIR radiation are silicon bolometers cooled to temperatures between 1.4 and 4 K. The beam splitters for the interferometer are made from Mylar. Optics used to focus the FIR radiation onto the sample is made from polyethylene or polypropylene.

The globar emits a broad spectrum of FIR radiation. A beam splitter divides the FIR radiation beam into two. One of the beams is reflected from a fixed mirror, whereas the other is reflected from a movable mirror. The path difference between the two beams is changed by moving the mirror. The beam splitter combines the two beams again and steers the FIR radiation to the detector. FIR-FTS measures the interferogram $I(s)$ of the two FIR radiation beams as a function of the path difference between the two beams. The spectrum $I(k)$ is obtained through calculation of the Fourier transform of the interferogram $I(s)$. For spectroscopy, the FIR radiation beam is focused onto a sample and the transmitted (or reflected) FIR radiation is detected. The illustration in Figure 8 is only a schematic of FIR-FTS. Various versions of two-beam interferometers for specific applications of FIR-FTS have been developed and are described in the literature.[14]

3.2 Backward-wave Oscillator Terahertz Spectrometer

The THz radiation source in a BWO THz spectrometer is a BWO,[17] which is an electron beam device. A cathode produces electrons via thermal emission. Subsequently, electrons are accelerated by applying high voltage toward an anode. An applied magnetic field focuses the electrons to a narrow beam. The electron beam interacts with a periodic metallic structure while traveling to the anode. Electromagnetic interactions between the electron beam and the metallic periodic structure result in the generation of THz radiation. The THz radiation is collected by a waveguide and coupled to free space by a horn antenna. The frequency of the THz radiation is determined by the electron velocity, which in turn depends on the applied accelerating voltage. The frequency of THz radiation emitted by a BWO is tunable. Continuous tuning of the THz radiation frequency is achieved by changing the applied voltage. The frequencies of typical BWOs are listed in Table 3. The THz radiation power of a BWO can be as high as 50 mW. The THz radiation power is characterized by high frequency stability $\Delta\nu/\nu = 10^{-5}$,

Table 3 Frequency range of operation and power of backward-wave oscillators

BWO	1	2	3	4	5	6	7
Frequency (THz)	0.035–0.055	0.05–0.08	0.08–0.12	0.12–0.18	0.18–0.26	0.26–0.37	0.37–0.53
THz power (mW)	40	30	30	50	10	10	5
BWO	7	8	9	10	11	12	13
Frequency (THz)	0.37–0.53	0.5–0.7	0.7–0.9	0.8–1.0	0.9–1.1	1.0–1.25	1.2–1.4

Figure 9 Schematics of a phase-sensitive BWO THz spectrometer.

high long-term power stability $\Delta P/P = 10^{-3}$, and high degree of linear polarization (100 : 1).

Phase-sensitive THz transmission and reflection spectroscopy with BWOs as the THz radiation source is illustrated in Figure 9. In transmission geometry, the THz radiation emitted by the BWO is collected by a lens and split into two beams by a wire-grid beam splitter. One beam is transmitted through the material to be analyzed and the second beam serves as a reference to measure the phase shift induced on the transmitted THz radiation wave by the material. The transmitted beam and the reference beam are combined by a second wire grid and focused on the detector. Depending on whether transmission or reflection measurements are performed, the measured quantities are the transmission coefficient T of the sample and the phase shift Φ_t of the transmitted wave or reflection coefficient R and phase shift Φ_r of the reflected beam. These measured quantities are directly related to the complex dielectric function $\varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega)$ and complex magnetic permeability $\mu(\omega) = \mu_1(\omega) + i\mu_2(\omega)$ of the material under investigation. For nonmagnetic materials, the two unknown quantities ε_1 and ε_2 are obtained from either a transmission or a reflection measurement. For magnetic materials, four unknown quantities have to be determined, ε_1, ε_2, μ_1, and μ_2, using the measured transmission and reflection coefficient and corresponding phase shifts.[32]

3.3 Time-domain Terahertz Spectrometer

A TD THz transmission spectrometer is powered by a femtosecond NIR laser and operates according to the pump–probe principle.[23,24,26] A schematic of the experimental arrangements is displayed in Figure 5. The pump–probe principle is briefly described as follows: The femtosecond NIR laser beam is split in two beams. One of the beams, the pump beam, hit the THz radiation source, which in response to the femtosecond laser pulse releases a pulse of THz radiation. The probe beam gates the THz detector whose response is proportional to the amplitude and the sign of the electric field of the THz pulse. The time profile of the THz pulse is traced by varying the time delay between the pump and probe beam. An example of a measured THz radiation pulse is illustrated in Figure 10. In this experiment, the THz radiation pulse traveled approximately 0.3 m through air with a residual water vapor concentration of $1.7 \times 10^{-3}\,\mathrm{kg\,m^{-3}}$. The Fourier transform of the THz radiation pulse is illustrated in Figure 11. The frequency spectrum extends from 0.45 to 2.5 THz. The Fourier transform shows that the dynamic range of the TD THz spectrometer is a function of frequency. The maximum of the dynamic range for measurements of the THz electric field is 800 : 1 at 0.3 THz. The spectrum in Figure 11 is the THz spectrum of air with a residual water vapor concentration of $1.7 \times 10^{-3}\,\mathrm{kg\,m^{-3}}$. In comparison, Figure 12 displays the spectrum of a THz radiation pulse, which traveled the same distance but through air with a residual water vapor

Figure 10 Time-domain measurement of a THz radiation pulse with a TD THz spectrometer. The THz signal is proportional to the amplitude of the THz electric field.

Figure 11 Spectrum of the THz radiation pulse. It is obtained by Fourier transformation of the time-domain measurement of the THz radiation pulse to the frequency domain. In this measurement, the THz radiation pulse propagated through 0.3 m of nitrogen (N_2) with a residual water vapor concentration of $1.7 \times 10^{-3}\,\mathrm{kg\,m^{-3}}$ at room temperature and atmospheric pressure. The dynamic range of the TD THz spectrometer is frequency dependent. The maximum of the dynamic range is at ≅0.3 THz.

Figure 12 Spectrum of another THz radiation pulse. Again, it is obtained by Fourier transformation of the time-domain measurement of the THz radiation pulse. In this measurement, the THz radiation pulse propagated through 0.3 m of nitrogen (N_2) with a residual water vapor concentration of $6.9 \times 10^{-3}\,\mathrm{kg\,m^{-3}}$ at room temperature and atmospheric pressure. The sharp dips in the spectrum correspond to water vapor absorptions lines in the THz frequency range.

concentration of $6.9 \times 10^{-3}\,\mathrm{kg\,m^{-3}}$. The narrow dips in transmission marked by an arrow correspond to absorption lines of water vapor in the THz frequency range below 1.5 THz. The transmission t of a sample placed in the focus of the THz beam is the ratio of the Fourier transforms of a THz pulse transmitted through the sample and the Fourier transform of a reference, e.g. a THz pulse freely propagating through air.

3.3.1 THz Radiation Emitters for Time-domain THz Spectrometers

THz radiation sources used in TD THz spectrometers are either semiconductors or nonlinear optical crystals. Terahertz radiation emission from semiconductors exposed to femtosecond NIR laser pulses originates either from a nonlinear optical process or from ultrafast photocurrents. Nonlinear optical processes resulting in THz radiation emission are bulk- or surface-field-induced optical rectification of the incident femtosecond NIR laser pulses. Generation of THz radiation pulses due to optical rectification of femtosecond laser pulses either in a semiconductor or in a nonlinear optical crystal is based on difference in frequency mixing of all frequencies within the bandwidth Δf of a femtosecond NIR laser pulse.[26] Terahertz radiation emission due to ultrafast photocurrents can be achieved through acceleration of photocarriers by intrinsic or extrinsic electric fields.[23,24] Intrinsic electric fields occurring at a semiconductor surface are surface depletion/accumulation fields or a photo-Dember field. Extrinsic electric fields are generated by applying laterally a voltage across a gap between two metal electrodes deposited on the semiconductor surface (photoconductive switch).

3.3.2 THz Radiation Detectors for Time-domain THz Spectrometers

The THz radiation detector in a TD THz spectrometer is either a photoconducting antenna or an electrooptic THz detector. A photoconducting antenna for the detection of the temporal waveform of THz radiation pulses consists of a thin-film antenna deposited on a thin semiconductor layer supported by an electrically insulating substrate, which is transparent at THz frequencies.[23,24] The semiconductor layer is manipulated such that it exhibits a high-dark resistivity and femtosecond carrier lifetime. Most commonly, ion-implanted silicon-on-sapphire (SOS) or low-temperature-grown GaAs (LT-GaAs) on semi-insulating GaAs is used for detector fabrication. The thin-film antenna is typically a center-fed dipole, which is approximately 50 μm long and 10 μm wide or a bipolar dipole antenna with 30-μm separation. Both types of antenna have a 5-μm-wide photoconducting gap in the center. A schematic of the experimental arrangements for photoconducting detection is displayed in Figure 13. For the detection, the femtosecond laser probe beam and the THz beam incident perpendicular onto the antenna from opposite sides. The probe beam is focused onto the photoconducting gap of the antenna. The THz radiation is incident through the substrate onto the antenna. The THz radiation is focused by a parabolic mirror and the coupling of the THz radiation to the substrate is enhanced by a small high-resistivity silicon lens that is attached to the substrate. The electrical field of the incident THz radiation couples to the antenna and induces a voltage across the photoconducting gap. A photocurrent $j(t)$ flows under the action of the induced voltage when the probe

Figure 13 Detection of THz radiation with photoconducting antennas in a TD THz spectrometer.

laser beam excites photocarriers in the photoconducting gap. This photocurrent is the convolution of the transient conductivity $\sigma(t)$ of the semiconductor and the electric field $E(t)$ across the photoconducting gap, as described in Equation (11). The magnitude and sign of the current $j(t)$ are proportional to the amplitude and phase of the electric THz field $E(t)$. The current is measured by a current amplifier.

$$j(t) = \int \sigma(t - t')E(t')\,\mathrm{d}t' \tag{11}$$

The temporal profile of the THz radiation pulse is measured by scanning the femtosecond laser pulse through the THz pulse by an optical delay line.

An alternative to photoconducting antennas for the measurement of the temporal waveform of a THz radiation pulse is electrooptic detection.[25,26] Electrooptic detection of THz radiation pulses relies on the fact that the electric field of a THz radiation beam, which passes through a nonlinear optical crystal such as a ZnTe crystal, induces birefringence in the crystal via the Pockel's effect.[34] This birefringence can be probed by a linearly polarized femtosecond laser pulse, which propagates collinearly with the THz beam through the ZnTe crystal. The phase difference $\Delta\Phi$ between the ordinary and extraordinary ray of the probe laser pulse is directly proportional to the electric THz field. In Equation (12), ω_{opt} is the angular frequency of the probe laser beam, n_0 is the index of refraction of the ZnTe crystal, r_{41} is the electrooptic coefficient of ZnTe, and Δx is the thickness of the ZnTe crystal.

$$\Delta\Phi = \frac{\omega_{\mathrm{opt}}}{c} {n_0}^3 r_{41} E_{\mathrm{THz}} \Delta x \tag{12}$$

Figure 14 Detection of THz radiation in a TD THz spectrometer by electrooptic sampling.

The experimental arrangements for electrooptic detection are displayed in Figure 14. The setup consists of a λ/2 plate, a Glan–Thomson polarizer, a pellicle beam splitter, a ZnTe crystal, a λ/4 plate, a Wollaston prism, and two photodiodes. Collinear propagation of the probe beam and of the THz beam in the ZnTe crystal is achieved through the pellicle beam splitter. The pellicle beam splitter is transparent for THz radiation but reflects optical light. The λ/2 plate allows a variation in the plane of polarization of the linearly polarized optical laser beam. The Glan–Thomson prism enhances the degree of linear polarization from 100 : 1 at the output of the Ti-sapphire laser to 10^6 : 1.

The induced birefringence of the ZnTe crystal changes the linear polarization of the optical probe pulse to elliptical polarization. Subsequently, the elliptical polarization is changed into a circular polarization by the λ/4 wave plate. The Wollaston prism spatially separates the two orthogonal components of the circularly polarized laser light. Finally, the intensity of each orthogonal component is individually detected by a photodiode. The difference in the photodiode output is measured by a lock-in amplifier. The THz electric field is proportional to the difference in the output of the two photodiodes. The temporal profile of the THz radiation pulse is measured again by scanning the femtosecond laser pulse through the THz radiation pulse.

3.3.3 Optics for Time-domain THz Spectrometers

The THz radiation is collected, steered, and focused with gold-plated off-axis parabolic mirrors. The mirrors have a typical diameter of 25–50 mm. The focal length of the mirrors is typically 25–300 mm. In order to achieve proper THz beam steering, it is important that the THz emitter, sample, and THz detector are accurately positioned at the focal points of the mirrors to avoid spatial transformations of the THz beams. As a result of spatial transformations, phase changes and frequency filtering of the pulse time profile may occur.[35]

4 OVERVIEW OF APPLICATIONS OF THz SPECTROSCOPY

Traditional areas of application of THz spectroscopy have been chemistry, materials science, and physics. A large body of work on THz spectroscopy of gases, liquids, and solids has been reported.[3,4,7,8,36–39] It is beyond the scope of this article to survey and summarize all this work.

As explained previously, FIR spectroscopy is a synonym of THz spectroscopy. Therefore, THz spectroscopy is infrared spectroscopy in the very low frequency range of the infrared (Figure 1). THz spectroscopy measures the dielectric function of materials in the THz frequency range. The dielectric function provides information on the dynamic properties of a material. All selection rules for infrared spectroscopy also apply to THz spectroscopy.

A very fruitful area of research has been THz spectroscopy of gases. Small polar molecules in the gas phase exhibit characteristic absorption lines in the microwave frequency range (Figure 1) and THz frequency range. The absorption frequencies of diatomic molecules with a permanent electric dipole moment are $f = 2h/(8\pi^2 I)(j+1)$, where $j = 0, 1, 2, 3, \ldots$, $h = 6.6 \times 10^{-34}$ Js, the moment of inertia is $I = \mu r^2$, the internuclear distance is r, and $\mu = m_1 m_2/(m_1 + m_2)$ the reduced mass of the molecule. Absorption due to excitation of rotations occurs for molecules with a small reduced mass μ. Examples are HF, HCl, H_2O, and NH_3. The vibration frequency of diatomic molecules is $\omega = 2\pi f = (k/\mu)^{1/2}$, where k is the force constant of the bond and μ is the reduced mass of the molecules. Vibrational frequencies of molecules are found in the THz frequency range for a large reduced mass (at least one heavy atom) or a weak force constant. Examples of weak force constants are atoms bound by hydrogen or van der Waals bonds. Examples of molecules with a large reduced mass are heavy-metal-to-metal or metal-to-ligand bonds.[3]

The understanding of rotational and vibrational transitions of molecules in the THz frequency range is important for the understanding of the transmission of the atmosphere in this frequency range.[38,39]

THz spectroscopy of biomolecules and pharmaceutical applications of THz spectroscopy are emerging as new areas of application.[40–42] A combination of THz spectroscopy and THz imaging is suggested as a novel medical imaging modality.[43]

This article is devoted to the fundamentals of infrared spectroscopy. While it is well known that infrared spectroscopy is an extremely important analytical technique, its theoretical basis is not easily assimilated by most analytical chemists. It must be admitted that a certain understanding of abstract concepts, such as those encountered in quantum mechanics, is required. However, with all apologies to the reader, it is the objective here to present the essentials of these ideas, as needed in analytical applications of infrared spectroscopy. It should be noted that most of these principles apply equally to Raman spectroscopy, a subject which is described in other articles.

It is the Born–Oppenheimer approximation that provides the theoretical basis for the analysis of infrared spectra. The rotational and vibrational degrees of freedom of a molecule are specified to allow the spectra of molecules in the gas phase to be interpreted. It is shown that the logical extension of these arguments can be employed in the analysis of the spectra of liquids and crystalline solids.

In later sections, an effort has been made to explain how the basic ideas developed earlier can be applied to the interpretation of the infrared spectra of hydrogen-bonded molecules, polymers and amorphous systems. A brief description of the notion of characteristic group frequencies, as routinely employed in organic chemistry, has been included to allow the practicing chemist to appreciate the possibilities – as well as the limitations – of this most important approach to the subject. To advance his appreciation of the advantages of infrared spectroscopy in analytical chemistry, the reader should refer to the various applications, as listed at the end of this article.

1 INTRODUCTION

The theoretical basis of the infrared spectroscopy of molecular systems is established by the analysis of the dynamics of the nuclear displacements. The Born–Oppenheimer approximation is of course the fundamental argument in the treatment of this problem. As the masses of the electrons and the nuclei in a molecule are significantly different, the much lighter electrons

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

move rapidly to create the so-called electron cloud which ''sticks'' the nuclei into relatively fixed equilibrium positions. The resulting geometry of the nuclear configuration is usually referred to as the molecular structure. It will be shown in this article that this molecular geometry plays an essential role in the determination of the vibrational and rotational spectra, both infrared and Raman, of a given molecule.

The analytical application of infrared spectroscopy can without doubt be founded on the work of Coblentz. His early publication, which has been reprinted, represents the most important contribution to the development of analytical applications of infrared spectroscopy.[1] However, the more practical or ''routine'' use of infrared spectroscopy as an analytical tool had to await the evolution of the necessary instrumentation, for a large part the result of military requirements during World War II. Thus, after a half century the early observations by Coblentz were confirmed and applied to what is now the field of analytical infrared spectroscopy. Initial applications were for the most part limited to the mid-infrared region, from 4000 to approximately $500\,\mathrm{cm}^{-1}$, by the instrumentation available. However, it is just this region that yields spectral features that can be identified, at least approximately, with organic functional groups. Furthermore, it is this region that is important in the analysis of molecular vibrations, as it is here that most vibrational fundamentals are observed. With the introduction of matrix methods, followed by the development of digital computers, the calculation of molecular force fields from observed vibrational spectra became possible. These results have provided invaluable information concerning the nature of the chemical bond.

The objective of this article is to summarize the theoretical basis of this important area of analytical chemistry. It must be admitted that the mathematical treatment of certain aspects can become rather demanding. An effort will be made to reduce these difficulties to a minimum, to allow the practicing analytical spectrocopist to appreciate the bases of the theoretical problem, without being obliged to delve into the mathematical details.

2 THE DIATOMIC MOLECULE

2.1 Kinetic Energy

The vibrational and rotational motions of a free diatomic molecule, as in an ideal gas, can be simply represented by the displacement of two point masses m_1 and m_2 in free space. The kinetic energy of the two-particle system is then given in Cartesian coordinates by Equation (1):

$$T = \tfrac{1}{2}[m_1(\dot{x}_1^2 + \dot{y}_1^2 + \dot{z}_1^2) + m_2(\dot{x}_2^2 + \dot{y}_2^2 + \dot{z}_2^2)] \qquad (1)$$

The introduction of the reduced mass μ, defined by Equation (2):

$$\frac{1}{\mu} = \frac{1}{m_1} + \frac{1}{m_2} \qquad (2)$$

allows the kinetic energy to be expressed as a function of the relative positions of the two particles. Furthermore, if the spherical coordinates r, θ, φ with respect to the center of mass are employed to describe the position of a hypothetical particle of mass μ, the Schrödinger equation for this system becomes (Equation 3)

$$-\frac{h^2}{8\pi^2\mu}\left[\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right) + \frac{1}{r^2\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial}{\partial\theta}\right) + \frac{1}{r^2\sin^2\theta}\frac{\partial^2}{\partial\varphi^2}\right]\psi + V(r)\psi = E\psi \qquad (3)$$

where h is Planck's constant. The usual procedure for the separation of independent variables can then be made by the introduction of Equation (4):

$$\psi(r,\theta,\varphi) = R(r)Y(\theta,\varphi) \qquad (4)$$

The functions $Y(\theta,\varphi)$ are the well-known spherical harmonics. The resulting expression for the r-dependent function is then of the following form (Equation 5):

$$-\frac{h^2}{8\pi^2\mu r^2}\frac{\mathrm{d}}{\mathrm{d}r}\left(r^2\frac{\mathrm{d}}{\mathrm{d}r}\right)R(r) + \frac{h^2J(J+1)}{8\mu r^2}R(r) + V(r)R(r) = ER(r) \qquad (5)$$

It is important to note that the second term in brackets contains the factor $J(J+1)$, which arises from the boundary conditions imposed on the spherical harmonics. The requirement that $J = 0, 1, 2, 3, \ldots$, has the effect of quantizing the angular momentum associated with the rotation of the diatomic molecule. Clearly, the solutions to Equation (5) depend on the form of the potential function which, in this case, governs the interaction between the two nuclei. The rotation of the system, which produces the centrifugal force, contributes the energy given by the second term in Equation (5). Thus, the square of the angular momentum is quantized according to Equation (6):

$$\mathcal{M}^2 = \frac{h^2}{4\pi^2}J(J+1) \qquad (6)$$

(see section 3.8).

To take the simplest case, suppose that the distance between the two masses is held constant, $r = r_e$. Then, as $V(r) = 0$, Equation (5) reduces to Equation (7):

$$E_{\mathrm{rot}} = \frac{h^2J(J+1)}{8\pi^2\mu r_e^2} \qquad (7)$$

Figure 1 The potential function for a diatomic molecule (solid curve) and the harmonic approximation (dashed curve).

where E_{rot} is the energy of the rigid rotor. This approximation is usually the first step in the interpretation of the pure rotational spectra of diatomic molecules, as observed in the microwave and far-infrared regions.

2.2 Potential Energy

According to the Born–Oppenheimer approximation, the effect of the electron cloud is to produce an interaction potential of the form shown by the solid curve in Figure 1. Although a number of empirical functions exist to represent this function, as a first approach, the harmonic approximation is employed. Here, the development of the potential function $V(r)$ is carried out in a Taylor series in the following form (Equation 8):

$$V(r) = V_0 + \left(\frac{dV}{dr}\right)_{r_e}(r - r_e) + \frac{1}{2}\left(\frac{d^2V}{dr^2}\right)_{r_e}(r - r_e)^2 + \cdots \tag{8}$$

As the origin of the potential energy scale is arbitrary, V_0 can be chosen equal to zero. The second term in Equation (8) vanishes, because the slope of the curve at the minimum, $r = r_e$, is of course zero. The first nonvanishing term is thus the quadratic term in $x = r - r_e$. In the harmonic approximation higher terms in this development are neglected and the potential function becomes (Equation 9)

$$V(r) = \tfrac{1}{2}f(r - r_e)^2 = \tfrac{1}{2}fx^2 \tag{9}$$

where the force constant f can be identified with the curvature of the potential function at the minimum.

The solution to the one-dimensional Schrödinger equation with the potential function given by Equation (9) leads to wave functions expressed as Hermite polynomials and the energy in the following form (Equation 10):

$$E_{\text{vib}} = h\nu_e(v + \tfrac{1}{2}) \tag{10}$$

where $v = 0, 1, 2, \ldots$ is the vibrational quantum number. The quantity $\nu_e = (1/2\pi)\sqrt{f/\mu}$ is equal to the vibrational frequency of the corresponding classical oscillator.[2]

2.3 Rigid Rotating Harmonic Oscillator

With the rotational energy given by Equation (7) and the vibrational energy given by Equation (10), the total energy takes the simple form of Equation (11):

$$E_{J,v} = E_{\text{rot}} + E_{\text{vib}} = \frac{h^2J(J+1)}{8\pi^2\mu r_e^2} + h\nu_e\left(v + \frac{1}{2}\right. \tag{11}$$

The practicing spectroscopist usually writes this expression as Equation (12):

$$\frac{E_{J,v}}{hc} = \bar{\nu}_e\left(v + \frac{1}{2}\right. + \overline{B}_eJ(J+1) \tag{12}$$

where $\overline{B}_e$ is the rotational constant expressed in cm^{-1} and $\bar{\nu}_e$ is the vibrational wavenumber, often referred to (incorrectly) as the vibrational "frequency". Equation (11) is represented by the energy-level diagram presented in Figure 2. The figure is not to scale, as the relative separation between the fundamental vibrational levels $v = 0$ and those of the excited state $v = 1$ is usually much greater than indicated.

A first approximation to the calculation of the rotation–vibration spectrum of a diatomic molecule can be made on the basis of Figure 2. It is sufficient to impose the selection rules $\Delta v = 1$ for vibrational absorption

Figure 2 The energy levels for a diatomic rigid rotator.

and $\Delta J = \pm 1$ for the accompanying rotational transitions, as shown. It is important to note that there is no transition that corresponds to the purely vibrational frequency, as the rotational transition $\Delta J = 0$ is forbidden by the rotational selection rules. This analysis indicates that the fundamental transition $v = 0 \Rightarrow v = 1$ should yield a series of equally spaced lines, with a missing element at the center, where $\Delta J = 0$ (see section 5.1).

2.4 Vibrating Rotator

The simple description presented above of the rotation–vibration spectrum of a diatomic molecule was based on the rigid rotator–harmonic oscillator approximation. However, if Equation (12) is generalized to include the anharmonicity of the vibration, in addition to the effects of centrifugal distortion and rotation–vibration coupling, it becomes (Equation 13)

$$\frac{E_{J,v}}{hc} = \bar{\nu}_e \left(v + \frac{1}{2} \right. + \overline{B}_e J(J+1) - \bar{\nu}_e x_e \left(v + \frac{1}{2} \right)^2 - \overline{D} J^2 (J+1)^2 - \bar{\alpha}_e \left(v + \frac{1}{2} \right. J(J+1) \qquad (13)$$

The various parameters appearing in Equation (13) can be evaluated from the rotation–vibration spectra of diatomic molecules or with the use of an empirical function to represent the curve shown in Figure 1. In the latter case, the Morse function (Equation 14)

$$V(r) = D_e[1 - e^{-a(r-r_e)}]^2 \qquad (14)$$

which is one of the simplest, usually yields satisfactory results.[2] In Equation (14) D_e is the energy of dissociation and the parameter a is $\sqrt{f/2D_e}$.

3 POLYATOMIC MOLECULES

Within the framework of the Born–Oppenheimer approximation the electronic energy of a molecule is considered to be a function of its instantaneous nuclear configuration. What is often referred to as the ''electronic problem'' is then the solution of the Schrödinger equation for the movement of the electrons for each fixed configuration of the N atoms in the molecule. The values of the energy as functions of the molecular configuration represent the effective potential function that governs the movement of the nuclei. The solutions to this problem yield the various possible values of the energy E_{nucl} for each electronic state of the molecule.

This energy, associated with the movement of the nuclei, is usually decomposed, at least in a first approximation, in the following form (Equation 15):

$$E_{nucl} = E_{trans} + E_{rot} + E_{vib} + \text{interactions} \qquad (15)$$

The interaction terms are not always negligible, although in analytical applications of vibrational spectroscopy it is usually an acceptable approximation. Furthermore, the translational contribution to the energy is in most cases classical. In other words, it does not have spectroscopic significance. In the case of solids, however – particularly at low frequencies – its effects should not be overlooked.

The conclusions of the above arguments are that for practical purposes the energy of an isolated molecule can be expressed as the sum of two terms, corresponding to its rotational and vibrational energies. This approximation is the initial step in the interpretation of the spectra of gases, as summarized in section 5. The rotation of molecules in condensed phases is restricted by the intermolecular forces. Thus, as a first approximation, the infrared and Raman spectra of liquids and solids can be analyzed with the consideration of only the vibrational energy of the system. However, the intermolecular forces often have important consequences, as they determine to a large extent the shapes of vibrational bands and are responsible for ''solvent effects'' in the spectra of solutions. These questions are considered later.

3.1 Vibrational Kinetic Energy

The vibrational energy of an isolated molecule will now be written as the sum of the kinetic and potential energies (Equation 16):

$$E_{vib} = T + V \qquad (16)$$

A set of $3N$ Cartesian displacement coordinates in the following form (Equation 17):

$$\xi = \begin{matrix} \Delta x_1 \\ \Delta y_1 \\ \Delta z_1 \\ \text{----} \\ \Delta x_2 \\ \Delta y_2 \\ \Delta z_2 \\ \text{----} \\ \cdot \\ \cdot \\ \cdot \\ \text{----} \\ \Delta x_N \\ \Delta y_N \\ \Delta z_N \end{matrix} \qquad (17)$$

can be employed to express the kinetic energy. If a diagonal matrix of the atomic masses is defined by Equation (18):

$$\boldsymbol{M} = \begin{matrix} m_1 & & & & & & & & \\ & m_1 & & & & & & & \\ & & m_1 & & & 0 & & & \\ & & & m_2 & & & & & \\ & & & & m_2 & & & & \\ & & & & & m_2 & & & \\ & & & & & & \cdot & & \\ & & & 0 & & & & m_N & \\ & & & & & & & & m_N \\ & & & & & & & & & m_N \end{matrix} \qquad (18)$$

the kinetic energy in terms of these matrices takes the compact form (Equation 19)

$$T = \tfrac{1}{2}\dot{\tilde{\boldsymbol{\xi}}}\boldsymbol{M}\dot{\boldsymbol{\xi}} \qquad (19)$$

where the dot over the vector defined by Equation (17) indicates that the time derivative has been taken and the tilde represents the transpose operation.

3.2 Internal Coordinates

It is usually convenient to work with a set of internal displacement coordinates, $\boldsymbol{S}$, as they have chemical significance. In the limit of small amplitudes of atomic displacements, the two sets of coordinates are linearly related. Thus (Equation 20),

$$\boldsymbol{S} = \boldsymbol{B}\boldsymbol{\xi} \qquad (20)$$

where the matrix $\boldsymbol{B}$ is determined by the equilibrium geometry of the molecule. Equation (19) allows the kinetic energy to be expressed in internal coordinates as Equation (21):

$$T = \tfrac{1}{2}\dot{\boldsymbol{S}}\boldsymbol{G}^{-1}\dot{\boldsymbol{S}} \qquad (21)$$

where the matrix $\boldsymbol{G}$ is defined by $\boldsymbol{G} \equiv \boldsymbol{B}\boldsymbol{M}^{-1}\boldsymbol{B}$. Although, in principle, the $\boldsymbol{G}$ matrix can be constructed with a knowledge of the atomic masses and the molecular geometry, tables of its elements are available that were developed many years ago.[3] In present-day computer programs, it is constructed and employed directly to calculate the vibrational frequencies and the specific forms of the normal modes of vibration, as summarized in the following sections.

3.3 Potential Energy

Although the equilibrium configuration of a molecule can usually be specified, at ordinary temperatures all of the atoms undergo oscillatory motions. The forces between the atoms in the molecule are described by a Taylor series of the intramolecular potential function in the internal coordinates. This function can then be written in the following form (Equation 22):

$$V = \frac{1}{2}\sum_{t,t'}\left(\frac{\partial^2 V}{\partial S_t \partial S_{t'}}\right)_0 S_t S_{t'} = \frac{1}{2}\sum_{t,t'} f_{t,t'} S_t S_{t'} \qquad (22)$$

an expression that includes the first nonzero terms in the expansion of the potential function with respect to the equilibrium configuration. Clearly, Equation (22) is a generalization of the harmonic potential for the diatomic molecule (Equation 9). Although higher terms in this series can be added to take into account the anharmonicity of the molecular vibrations, the harmonic approximation is employed in most practical calculations of the vibrational frequencies of a polyatomic molecule. Equation (22) can be written in matrix form as Equation (23):

$$V = \tfrac{1}{2}\boldsymbol{S}\boldsymbol{F}\boldsymbol{S} \qquad (23)$$

where $\boldsymbol{F}$ is a symmetric matrix of the force constants. Although the force constants can in principle be calculated from the molecular electronic wave functions, the results are not yet quantitatively reliable. These quantities are usually treated as variable parameters in the vibrational problem. Their evaluation from experimental spectroscopic data is of importance, both as a means of testing the results of ab initio electronic calculations and for their chemical significance. For example, the knowledge of the value of a force constant associated with the stretching of a chemical bond provides some insight into the nature of the bond, including semiquantitative measures of both its length and its dissociation energy.

3.4 Normal Coordinates

It is now fundamental to define the normal coordinates of this vibrational system – that is to say, the nuclear displacements in a polyatomic molecule. Again in the limit of small amplitudes of vibration, the normal coordinates in the form of the vector $\boldsymbol{Q}$ are related to the internal coordinates by a linear transformation, viz. (Equation 24)

$$\boldsymbol{S} = \boldsymbol{L}\boldsymbol{Q} \qquad (24)$$

The kinetic and potential energies given by Equations (21) and (23) become (Equation 25)

$$T = \tfrac{1}{2}\dot{\boldsymbol{S}}\boldsymbol{G}^{-1}\dot{\boldsymbol{S}} = \tfrac{1}{2}\dot{\boldsymbol{Q}}\boldsymbol{L}\boldsymbol{G}^{-1}\boldsymbol{L}\dot{\boldsymbol{Q}} = \tfrac{1}{2}\dot{\boldsymbol{Q}}\boldsymbol{E}\dot{\boldsymbol{Q}} \qquad (25)$$

and (Equation 26)

$$V = \tfrac{1}{2}\boldsymbol{SFS} = \tfrac{1}{2}\boldsymbol{QLFLQ} = \tfrac{1}{2}\boldsymbol{Q\Lambda Q} \tag{26}$$

respectively. The matrices $\boldsymbol{E}$ and $\boldsymbol{\Lambda}$ are both diagonal. The former is the unit matrix, while the latter is composed of elements $\boldsymbol{\lambda}_k = 4\pi^2 v_k^2$. The vibrational frequencies are given by v_k, where the subscript k identifies the normal mode of vibration. An inspection of Equations (25) and (26) identifies the role of the normal coordinates, namely, to eliminate simultaneously all cross-terms in the expressions for the kinetic and potential energies. This condition can be taken as the definition of the normal modes of vibration.

3.5 Secular Determinant

The last step in the calculation of the frequencies of molecular vibrations, as observed in the infrared spectra, is carried out by combining Equations (25) and (26). The vibrational energy of a polyatomic molecule is then given in this, the harmonic approximation, by Equation (27):

$$E_{\text{vib}} = T + V = \tfrac{1}{2}\dot{\boldsymbol{Q}}\boldsymbol{E}\dot{\boldsymbol{Q}} + \tfrac{1}{2}\boldsymbol{Q\Lambda Q} \tag{27}$$

From Equations (25) and (26), it is apparent that $\boldsymbol{LG^{-1}L = E}$ and $\boldsymbol{LFL = \Lambda}$. With the definition of the **G**-matrix, $\boldsymbol{L = L^{-1}G}$. Therefore (Equation 28),

$$\boldsymbol{L^{-1}GFL = \Lambda} \tag{28}$$

Hence, as is often stated, the determination of the normal coordinates is equivalent to the successful search for a matrix $\boldsymbol{L}$ that diagonalizes the product $\boldsymbol{GF}$ via a similarity transformation. This system of linear, simultaneous, homogeneous equations can be written in the following form (Equation 29):

$$\sum_{t'}[(\boldsymbol{GF})_{tt'} - \delta_{tt'}\lambda_k]L_{t'k} = 0 \tag{29}$$

where the Kronecker delta is defined by Equation (30):

$$\delta_{tt'} = \begin{cases} 1, & \text{if } t = t' \\ 0, & \text{if } t \neq t' \end{cases} \tag{30}$$

This set of equations for the elements of $\boldsymbol{L}$ can be resolved by application of Cramer's rule. Then, a nontrivial solution exists only if the determinant of the coefficients vanishes, or (Equation 31)

$$|\boldsymbol{GF} - \boldsymbol{E}\lambda_k| = 0 \tag{31}$$

This condition on the so-called secular determinant is the basis of the vibrational problem. The roots of Equation (31), λ_k, are the eigenvalues of the matrix product $\boldsymbol{GF}$, while the columns of $\boldsymbol{L}$, the eigenvectors, determine the forms of the normal modes of vibration. These relatively abstract relations become more evident with the consideration of an example.

3.6 The Water Molecule

As a simple illustration of the development of the secular determinant, consider the water molecule. A reasonable set of internal coordinates consists of the changes in lengths of the two bonds and the variation in the bond angle. Thus, from Equation (20) and Figure 3 (Equation 32)

$$\boldsymbol{S} = \begin{pmatrix} \Delta r_1 \\ \Delta r_2 \\ \Delta\alpha \end{pmatrix} = \boldsymbol{B}\boldsymbol{\xi}$$

$$= \left(\begin{array}{ccc:ccc:ccc} 0 & -s & -c & 0 & 0 & 0 & 0 & s & c \\ 0 & 0 & 0 & 0 & s & -c & 0 & -s & c \\ 0 & -c/r & s/r & 0 & c/r & s/r & 0 & 0 & -2s/r \end{array}\right) \begin{matrix} \Delta x_1 \\ \Delta y_1 \\ \Delta z_1 \\ \hdashline \Delta x_2 \\ \Delta y_2 \\ \Delta z_2 \\ \hdashline \Delta x_3 \\ \Delta y_3 \\ \Delta z_3 \end{matrix} \tag{32}$$

where $s = \sin\alpha/2$, $c = \cos\alpha/2$ (α being the equilibrium bond angle) and r is the equilibrium O–H bond length, as shown in Figure 3. The masses of the hydrogen and oxygen atoms are arranged according to Equation (18) in the order established by the vector $\boldsymbol{\xi}$, namely (Equation 33),

$$\boldsymbol{M} = \begin{pmatrix} m_{\text{H}} & & & & & & & & \\ & m_{\text{H}} & & & & & & & \\ & & m_{\text{H}} & & & 0 & & & \\ & & & m_{\text{H}} & & & & & \\ & & & & m_{\text{H}} & & & & \\ & & & & & m_{\text{H}} & & & \\ & & 0 & & & & m_{\text{O}} & & \\ & & & & & & & m_{\text{O}} & \\ & & & & & & & & m_{\text{O}} \end{pmatrix} \tag{33}$$

Figure 3 Internal coordinates for the water molecule.

The $\boldsymbol{G}$ matrix, as calculated from its definition, becomes (Equation 34)

$$\boldsymbol{G} = \boldsymbol{B}\boldsymbol{M}^{-1}\boldsymbol{B}$$

$$= \begin{matrix} \mu_H + \mu_O & \mu_O \cos\alpha & -\dfrac{\mu_O \sin\alpha}{r} \\ \mu_O \cos\alpha & \mu_H + \mu_O & -\dfrac{\mu_O \sin\alpha}{r} \\ -\dfrac{\mu_O \sin\alpha}{r} & -\dfrac{\mu_O \sin\alpha}{r} & \dfrac{2\mu_H + 2\mu_O(1-\cos\alpha)}{r^2} \end{matrix} \tag{34}$$

where $\mu_H = 1/m_H$ and $\mu_O = 1/m_O$.

The force-constant matrix based on internal coordinates is of the following form (Equation 35):

$$\boldsymbol{F} = \begin{matrix} f_r & f_{rr} & f_{r\alpha} \\ f_{rr} & f_r & f_{r\alpha} \\ f_{r\alpha} & f_{r\alpha} & f_{\alpha\alpha} \end{matrix} \tag{35}$$

where f_r is the coefficient of $(\Delta r_1)^2$ and $(\Delta r_2)^2$, and f_α is the coefficient of $(\Delta\alpha)^2$ in the potential energy expression. These constants are referred to as the principal or valence force constants. The off-diagonal constant f_{rr} represents an interaction constant which is the coefficient of $(\Delta r_1 \Delta r_2)$ and $(\Delta r_2 \Delta r_1)$ in the potential energy expression, while the interaction constant $f_{r\alpha}$ is the coefficient of all four terms of the type $(\Delta r_1 \Delta\alpha)$. By taking the product of the above matrices $\boldsymbol{G}$ and $\boldsymbol{F}$, the secular equation in the form of Equation (31) can be readily found.

In the construction of the matrix $\boldsymbol{F}$ of Equation (35), the symmetrical equivalence of the two O–H bonds was taken into account. Nevertheless, it contains four independent force constants. As the water molecule has only three fundamental vibrational frequencies, at least one interaction constant must be neglected or some other constraint introduced. If all of the off-diagonal elements of $\boldsymbol{F}$ are neglected, the two principal constants, f_r and f_α, constitute the valence force field (VFF) for this molecule. However, to reproduce the three observed vibrational frequencies this force field must be modified to include the interaction constant f_{rr}. This example will be reconsidered in section 4.7, after the question of molecule symmetry has been treated.

3.7 Molecular Rotation

The rotational energy of a molecule can be written in the following form (Equation 36):

$$E_{\text{rot}} = \tfrac{1}{2}\boldsymbol{\omega}\boldsymbol{I}\boldsymbol{\omega} \tag{36}$$

where it has been assumed that the molecule acts as a rigid rotator. In effect, in the limit of infinitesimal vibrational amplitudes, the moment of inertia tensor, $\boldsymbol{I}$, which becomes equal to that of a rigid rotator, is of the following form (Equation 37):

$$\boldsymbol{I} = \begin{matrix} I_{xx} & I_{xy} & I_{xz} \\ I_{yx} & I_{yy} & I_{yz} \\ I_{zx} & I_{zy} & I_{zz} \end{matrix} \tag{37}$$

The Cartesian coordinates employed in Equation (37) have been assumed to be attached to the rigid, rotating molecule. It should be noted that the moment of inertia tensor is symmetric with respect to the principal diagonal; thus, $I_{xy} = I_{yx}$, etc. The angular velocity associated with the rotation of the molecule is represented here by the vector $\boldsymbol{\omega}$. Equation (36) can then be written out in the following form (Equation 38):

$$E_{\text{rot}} = \tfrac{1}{2}[I_{xx}w_x^2 + I_{yy}w_y^2 + I_{zz}w_z^2 + 2I_{xy}w_x w_y + 2I_{yz}w_y w_z + 2I_{zx}w_z w_x] \tag{38}$$

It is in general possible to find a Cartesian coordinate system attached to the molecule such that the tensor I takes a diagonal form. In terms of these so-called principal axes Equation (38) is simplified in that all cross-terms are eliminated (Equation 39):

$$E_{\text{rot}} = \tfrac{1}{2}(I_a w_a^2 + I_b w_b^2 + I_c w_c^2) \tag{39}$$

The definition of the principal axes labeled a, b, c is usually dictated by the symmetry properties of the molecule (see section 4.5).

3.8 Classification of Rotators

With the use of principal axes it becomes possible to classify the types of rotator as follows:

1. linear: $I_a = I_b \neq I_c = 0$;
2. spherical: $I_a = I_b = I_c \neq 0$;
3. symmetric: $I_a = I_b \neq I_c \neq 0$;
4. asymmetric: $I_a \neq I_b \neq I_c$.

Within the framework of the rigid-rotor approximation, it then becomes possible to express in closed form the energy of each of the first three types of rotator. From Equation (36) with the angular velocity given by $\boldsymbol{\omega} = \begin{pmatrix} w_a \\ w_b \\ w_c \end{pmatrix}$, the rotational energy can be written in the following form (Equation 40):

$$E_{\text{rot}} = \frac{1}{2}\boldsymbol{\omega}\boldsymbol{I}\boldsymbol{\omega} = \frac{1}{2}\left(\frac{{}^{2}_{a}}{I_a} + \frac{{}^{2}_{b}}{I_b} + \frac{{}^{2}_{c}}{I_c}\right. \tag{40}$$

where ${}_a$, ${}_b$ and ${}_c$ are the components of the angular momentum with respect to the principal axes a, b and c, respectively.[3,4]

In the quantum-mechanical treatment of the rotational problem, it is shown that the square of the total angular momentum is quantized,[3,4] namely (Equation 41)

$$\mathcal{M}^2 = \quad {}^2_a + \quad {}^2_b + \quad {}^2_c = \frac{h^2}{4\pi^2} J(J+1) \qquad (41)$$

where the rotational quantum number is defined by $J = 0, 1, 2, 3, \ldots$ (see section 2.1).

3.8.1 Linear Rotators

If c is chosen as the unique axis of a linear molecule, $\quad_c = 0$ and the rotational energy is given by Equation (42):

$$E_{\text{rot}} = \frac{h^2}{8\pi^2 I} J(J+1) \qquad (42)$$

where $I = I_a = I_b$ is the moment of inertia of the molecule. It should be noted that there is a degeneracy equal to $2J + 1$, as the quantum number $M = 0, \pm 1, \pm 2, \ldots, \pm J$.

3.8.2 Spherical Rotators

If the principal moments of inertia are equal, viz. $I = I_a = I_b = I_c$, Equation (36) leads to the same expression for the energy as given by Equation (42), i.e. (Equation 43)

$$E_{\text{rot}} = \frac{h^2}{8\pi^2 I} J(J+1) \qquad (43)$$

where, as above, I is the moment of inertia of the molecule at equilibrium. Then, as $\quad_c = (h/2\pi)K$, where the additional quantum number $K = 0, \pm 1, \pm 2, \ldots, \pm J$, the resulting degeneracy is equal to $(2J + 1)^2$.

3.8.3 Symmetric Rotators

In this case the principal moments are related by $I = I_a = I_b \neq I_c \neq 0$, where again the c-axis has been chosen as the unique direction. The classical rotational energy can then be given as Equation (44):

$$E_{\text{rot}} = \frac{{}^2_a + \quad {}^2_b}{2I_a} + \frac{{}^2_c}{2I_c} = \frac{\mathcal{M}^2}{2I_a} + \frac{{}^2_a}{2}\left(\frac{1}{I_c} - \frac{1}{I_a}\right. \qquad (44)$$

With the use of the relations given above, the quantum-mechanical expression becomes (Equation 45)

$$E_{\text{rot}} = \frac{h^2}{8\pi^2 I_a} J(J+1) + \frac{h^2 K^2}{8\pi^2}\left(\frac{1}{I_c} - \frac{1}{I_a}\right. \qquad (45)$$

Equation (45) allows two types of symmetric rotator to be defined. If $I_c < I_a$, the rotator is elongated in the direction of the c-axis. It is said to be a prolate top, as, say, an American football. The second term on the right-hand side of Equation (45) is then positive. On the other hand, if $I_c > I_a$, the rotator is flattened with respect to the c direction, as the earth – or in the limit, a pancake. In this case the second term on the right-hand side of Equation (45) is negative and the rotator is an oblate top. These two types of rotator can usually be distinguished in their rotation–vibration spectra by the contribution of the second term. The degeneracy for this class of rotator is rather complicated, viz. $2J + 1$ if $K = 0$ and $2(2J + 1)$ if $|K| > 0$ (see section 5.3).

3.8.4 Asymmetric Rotators

In the most general case, all three principal moments of inertia are different: $I_a \neq I_b \neq I_c$. Unfortunately, most molecules fall into this class. No analytical expression can be written for the rotational energy of an asymmetric rotator. However, extensive tables for the energy levels were calculated many years ago. More recently, computer programs have been developed to carry out their numerical evaluation for a given molecular structure.

4 MOLECULAR SYMMETRY

Although all molecules are in constant thermal motion, when all of their atoms are in their equilibrium positions, a specific geometrical structure can usually be defined. The normal modes of vibration of such a structure, and hence an interpretation of its vibrational spectrum, can then be calculated – at least in the harmonic approximation.

4.1 Symmetry Elements

The mathematical description of the structure of a molecule is based on an application of group theory. It is necessary, then, to define certain symmetry operations. Although there are various ways of specifying these operations, geometrical descriptions are certainly the easiest to understand. Each symmetry operation (aside from the trivial one, E, the identity) is associated with an element of symmetry. Thus, for example, certain molecules are said to be planar. Well-known examples are water, boron trifluoride and benzene, whose structures can be drawn in the forms shown in Figure 4(a–c).

Figure 4 Planar molecules: (a) water; (b) boron trifluoride; (c) benzene.

The symmetry operations and their descriptions, and the notation established by Schönflies, are given in Table 1. To identify the symmetry group it is necessary to visualize all of the operations which characterize the structure of the molecule. As there is always at least one point in space that is not affected by any of these operations, the group is referred to as a point group. Usually with experience, and the aid of molecular models, the symmetry operations are not too difficult to find.

The molecules shown in Figure 4(a–c) are planar; thus, the paper on which they are drawn is an element of symmetry and the reflection of all points through the plane yields an equivalent (superposable) structure. The process of carrying out the reflection is referred to as the symmetry operation σ. However, as the atoms of these molecules are essentially point masses, the reflection operations result simply in the inversion of the direction (the coordinate) perpendicular to the plane.

In general, a molecule may have a number of elements of symmetry. For example, the water molecule has, in addition to the plane of symmetry indicated above, a second perpendicular to the first. The reflection operation with respect to this plane inverts the y direction, as well as interchanging the identification of the hydrogen atoms (see Figure 5).

The presence of two perpendicular planes of symmetry implies the existence of another element of symmetry,

Table 1 Operations used to describe molecular symmetry

Symmetry operation	Symbol	Symmetry element
Identity	E	–
Reflection in a plane	σ	Plane of symmetry
Rotation k times by $\theta = 2\pi/n$	C_n^k	Proper rotation axis of order n
Rotation by $\theta = 2\pi/n$ followed by a reflection in the plane $\perp$ to the axis	S_n^k	Improper rotation axis of order n
Inversion with respect to a center	$i \equiv S_{2k}^k$ (k odd)	Center of symmetry

Figure 5 The planes of symmetry in the water molecule.

Figure 6 The symmetry elements of the ethane molecule.

the twofold axis. It is an example of a binary rotation axis, denoted by the symbol C_2, which is in this case collinear with the z-axis in Figure 5.

Examples of the other symmetry elements shown in Table 1 are illustrated in Figure 6. For the ethane molecule in the staggered configuration, the vertical (z) axis is collinear with the ternary axis C_3 and a rotation–reflection axis, S_6. The symmetry of this molecule is also characterized by a center of inversion, i, as well as the plane of symmetry σ, as shown (Figure 6), and two similar ones designated σ' and σ''.

It should be apparent that more than one operation can be associated with each symmetry element. In the case of the ethane molecule considered above, the rotation about the C_3 axis by 120° can be carried out once or twice, as C_3^1 or C_3^2, respectively. However, the operation C_3^3 need not be considered as it corresponds to the identity, E, defined below. Similarly, after some reflection it is found that $S_6^2 \equiv C_3^1$, $S_6^3 \equiv i$ and $S_6^4 \equiv C_3^2$.

4.2 Group Theory

Without entering into the mathematical details, it is important to point out that the ensemble of symmetry operations that characterizes the structure of a molecule forms a group.[5,6] That is,

1. The combination of any two members of the ensemble is an element of the ensemble.
2. There is one element of the ensemble which permutes with all of the others and leaves them unchanged. It is known as the identity, E (German: Einheit).
3. The associative law of combination is valid.
4. Each element of the ensemble has an inverse that is also a member of the ensemble.

In (1), the combination of two members of the ensemble, that is, two symmetry operations, implies their successive application. It should be noted that in general these operations do not commute. The number of independent symmetry operations in a group is called the order of the group.

4.3 Coordinate Transformations

In the foregoing discussion, the symmetry operations have been described as ''rotations'', ''reflections'', etc. that is, as dynamic operations. However, strictly, symmetry operations are really coordinate transformations that modify the mathematical statement of the atomic positions, rather than the positions themselves. Furthermore, these transformations are subject to the condition that they cannot modify the potential energy of the molecule. This property follows from the fact that any coordinate system is merely a bookkeeping scheme without physical significance.

Returning to the water molecule as an example, the Cartesian displacement coordinates as given in Equation (32), are of the following form (Equation 46):

$$\boldsymbol{\xi} = \begin{matrix} \Delta x_1 \\ \Delta y_1 \\ \Delta z_1 \\ \text{----} \\ \Delta x_2 \\ \Delta y_2 \\ \Delta z_2 \\ \text{----} \\ \Delta x_3 \\ \Delta y_3 \\ \Delta z_3 \end{matrix} \tag{46}$$

for this triatomic system. A symmetry operation $\boldsymbol{R}$ results in a coordinate transformation (Equation 47):

$$\boldsymbol{\xi}' = \boldsymbol{R}\boldsymbol{\xi} \tag{47}$$

to form the vector $\boldsymbol{\xi}'$. Specifically, for the reflection $\boldsymbol{R} = \sigma(zx)$ the matrix representation is given by Equation (48):

$$\boldsymbol{R} = \left[\begin{array}{ccc:ccc:ccc} 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ \hdashline 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ \hdashline 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{array}\right] \tag{48}$$

The nine-by-nine matrix that represents a given operation $\boldsymbol{R}$ is composed of three-by-three submatrices, as shown. Those submatrices that lie along the principal diagonal contain nonzero elements if the coordinates of the atom in question are not permuted by the operation. Thus, in this example it is apparent that in Equation (48) the submatrix associated with the oxygen atom remains along the diagonal, while those for the two equivalent hydrogen atoms are displaced.

It is perhaps not surprising that the specific form of a matrix representation, such as that given in Equation (48), depends on the chosen basis coordinates – in this case the elements of the vector $\boldsymbol{\xi}$. However, there is always one quantity that is invariant, namely the trace of the representation matrix, that is, the sum of its diagonal elements. In group theory it is known as the character, as it characterizes the representation.

Each submatrix $\boldsymbol{R}_i$ appearing in a representation such as $\boldsymbol{R}$ in the above example can be written in the following general form (Equation 49):

$$\boldsymbol{R}_i = \begin{bmatrix} \cos\theta_j & -\sin\theta_j & 0 \\ \sin\theta_j & \cos\theta_j & 0 \\ 0 & 0 & \pm 1 \end{bmatrix} \tag{49}$$

where $\theta_j = 2\pi/n$ is the angle of (counterclockwise) rotation for a given symmetry operation (or class of symmetry operation), as given in Table 1. Then, for each atom i the contribution to the character of the representation is given by Equation (50):

$$\text{Trace } \boldsymbol{R}_i = (2\cos\theta_j \pm 1) \tag{50}$$

where in Equations (49) and (50) the positive sign is employed for the so-called proper operations (E and C_n) and the negative sign for the improper ones (σ, S_n and i). Clearly, for the example of the operation σ, Equation (50) yields $2\cos 0 - 1 = 1$ for the trace of the submatrix for the oxygen atom (see Equation 48). This result can be generalized to obtain the following expression for the character of the representation of any symmetry operation (Equation 51):

$$\chi_j = m_j(2\cos\theta_j \pm 1) \tag{51}$$

where m_j is the number of atoms in the molecule that are not permuted by the symmetry operations of class j. This relation, which is independent of any choice of basis coordinates, will be applied repeatedly in the following applications.

4.4 Irreducible Representations

As indicated above, there may be many – even an infinity – of matrix representations of a given symmetry operation, depending on the choice of basis coordinates. However, there exists a particular set of basis coordinates in terms of which the representation matrix is reduced to block-diagonal form. This result is shown symbolically in Figure 7. Each submatrix $\boldsymbol{\Gamma}^{(k)}$ is called an irreducible representation (IR), as there exist no

Figure 7 The form of a reduced representation.

basis coordinates that can result in a further reduction. Here, for example, the arbitrarily chosen first IR occurs three times, the second once and the third once again. In this figure the smaller squares ($k = 1, 2$) indicate one-dimensional matrices, while $\mathbf{\Gamma}^{(3)}$ is an IR of order two.

The result shown schematically in Figure 7 can be expressed mathematically in the following form (Equation 52):

$$\mathbf{\Gamma} = \sum_{\gamma} n^{(\gamma)} \mathbf{\Gamma}^{(\gamma)} \tag{52}$$

if it is understood that the summation is special. It indicates that the direct sum is to be taken, that is, the various IRs are arranged along the diagonal of the reduced representation. Each IR, identified by the superscript (γ), may appear more than once, or not at all. Thus, $n^{(\gamma)}$ is equal to the number of times that the IR $\mathbf{\Gamma}^{(\gamma)}$ appears in the reduced representation.

While it is not, in general, necessary to find the explicit forms of the IR matrices, their characters are readily available from standard tables. This information is sufficient for the resolution of most problems encountered in molecular spectroscopy.

4.5 Character Tables

The tables of the characters of the IRs have the general form shown in Table 2. For a point group the columns are headed by the symbols $_j$, the classes of symmetry operation. Each class may be composed of one or more symmetry operations, although by tradition the arbitrarily chosen first class consists uniquely of the identity operation, E. The rows are labeled by the identification of the IRs. In a given IR the operation E corresponds to a unit matrix whose order is equal to the dimension of the representation. Hence the resulting character is equal to the dimension of the representation and the dimension of each IR can be easily determined by inspection of the first column of characters in the table. It should be noted that the matrix of characters is square, that is, the number of IRs is equal to the number of classes of symmetry operation.

A further property of the character tables arises from the fact that every symmetry group has an IR that is invariant under all of the group operations. This IR is a one-by-one matrix composed of the number one for every class of operation. Obviously, the characters, are all then equal to one. As this IR is by convention taken to be $\mathbf{\Gamma}^{(1)}$, the first row of each character table consists solely of ones. The significance of the character tables will become more apparent by consideration of an example.

The water molecule in its equilibrium configuration is represented in Figure 5. The symmetry elements $\sigma(zx)$ and $\sigma(yz)$ are shown. The intersection of these two planes is the z-axis, which is collinear with the binary axis of symmetry, C_2. The symmetry operations with respect to these elements, plus of course the identity E, define the group $_{2v}$ in the notation of Schönflies. It is then said that the water molecule "belongs" to the symmetry group $_{2v}$.

The water molecule has $3N = 9$ degrees of freedom. Of these, three describe the position in space of the center of mass of the molecule, as specified by a vector with components T_x, T_y and T_z. Similarly, the angular momentum vector associated with the rotation of the molecule, is identified by its components R_x, R_y and R_z. These coordinates, which represent the six external degrees of freedom, are classified for molecules of $_{2v}$ symmetry in Table 3.

The classification of rotators made in section 3.8 can now be reconsidered in terms of the symmetry elements defined in Table 1. If a molecule has one symmetry

Table 2 The general form of a character table

	$_1 = E$	$_2$	$_3$	$\cdots$	$_k$
$\mathbf{\Gamma}^{(1)}$	$\chi_1^{(1)}$	$\chi_2^{(1)}$	$\chi_3^{(1)}$	$\cdots$	$\chi_k^{(1)}$
$\mathbf{\Gamma}^{(2)}$	$\chi_1^{(2)}$				
$\mathbf{\Gamma}^{(3)}$	$\chi_1^{(3)}$				
$\vdots$	$\vdots$				
$\mathbf{\Gamma}^{(k)}$	$\chi_1^{(k)}$	$\cdots$	$\cdots$	$\cdots$	$\chi_k^{(k)}$

Table 3 The character table for the point group $_{2v}$ and the analysis of the water molecule

$_{2v}$	E	C_2	$\sigma\,(zx)$	$\sigma\,(yz)$		$n^{(\gamma)}$ (tot)	$n^{(\gamma)}$ (vib)
$\mathbf{\Gamma}^{(1)} = A_1$	1	1	1	1	T_z	3	2
$\mathbf{\Gamma}^{(2)} = A_2$	1	1	−1	−1	R_z	1	0
$\mathbf{\Gamma}^{(3)} = B_1$	1	−1	1	−1	T_x, R_y	2	0
$\mathbf{\Gamma}^{(4)} = B_2$	1	−1	−1	1	T_y, R_x	3	1
χ_j	9	−1	1	3			

axis of threefold or higher symmetry, it is a symmetric rotator. Two angular momentum components will appear together, e.g. (R_x, R_y) in a doubly degenerate IR. If the molecule has two or more axes of greater than twofold symmetry, it is a spherical rotator, and all three components will be grouped in a three-dimensional IR. Clearly, the water molecule is an example of an asymmetric rotator.

4.6 Reduction of a Representation: The "Magic Formula"

The relation between a reducible representation and the IRs is given by Equation (52). In practical applications, it is essential to determine the values of $n^{(\gamma)}$, the number of times that each IR enters the direct sum shown in Figure 7. As χ_j is merely the sum of the diagonal elements of Γ for each class of operation j, it is also equal to the sum of the traces of the individual submatrices $\Gamma^{(\gamma)}$, each multiplied by $n^{(\gamma)}$. It follows that (Equation 53)

$$\chi_j = \sum_{\gamma=1}^{k} n^{(\gamma)} \chi_j^{(\gamma)} \quad j = 1, 2, \ldots, k \tag{53}$$

where $\chi_j^{(\gamma)}$ is the character of the IR $\Gamma^{(\gamma)}$ of an operation of the class $_j$. This set of simultaneous equations can be solved with aid of the orthogonality properties of the characters. The result is given by Equation (54):

$$n^{(\gamma)} = \frac{1}{g} \sum_{j=1}^{k} g_j \chi_j^{(\gamma)^*} \chi_j \tag{54}$$

This expression is of such widespread applicability that it is often referred to as the "magic formula". In it, g is the order of the group, that is, the total number of independent symmetry operations. The characters for each class of operation $\chi_j^{(\gamma)}$, are given in the character table for the symmetry group of the molecule, while χ_j is the corresponding character of the reducible representation. The latter can be calculated, for example, from Equation (51). Each product in the summation appearing in Equation (54) is weighted by the quantity g_j, the number of independent symmetry operations in each class.[3,6]

4.7 Examples

In spite of the apparent complexity of the magic formula, its application is fairly simple, as shown in the following examples. The water molecule was described above, where it was indicated that it is of symmetry $_{2v}$. The character table is presented in Table 3, where it is seen that the order of the group is equal to four and that each class is composed of only a single symmetry operation. The characters for the reducible representation, as calculated with the use of Equation (51), are shown in the last line of Table 3. Thus, Equation (54) yields the values of $n^{(\gamma)}$(tot) given in the first column to the right of the character table. This result indicates that the symmetry of the $3N$ degrees of freedom of the water molecule (or any triatomic molecule of symmetry $_{2v}$) can be described by the direct sum ($\oplus$) of IRs (Equation 55):

$$\Gamma = 3A_1 \oplus A_2 \oplus 2B_1 \oplus 3B_3 \tag{55}$$

As indicated above, for the $3N - 6$ normal vibrations of a nonlinear molecule in free space, the coordinates of translation and rotation can be removed. The symmetry of these external coordinates, T_x, T_y, T_z and R_x, R_y, R_z, is given in each character table. The difference for this example, $2A_1 \oplus B_2$, describes the symmetry of the three normal modes of vibration of the molecule. Two of them are symmetric with respect to all four of the symmetry operations of the point group. However, the mode of species B_2 is antisymmetric under the operations C_2 and $\sigma(zx)$, as shown in Table 3.

As a second example, the symmetry elements of the ethane molecule in its staggered conformation are illustrated in Figure 6. The ensemble of 12 symmetry operations forms the group $_{3d}$, whose character table is presented in Table 4. Note that in this case the IRs E_g and E_u are doubly degenerate, as indicated by the number two in the column headed E, the identity. The characters of the reducible representations are given in the last line. As in the previous example, the structure of the reduced representation is determined by the values of $n^{(\gamma)}$(tot) determined by application of the magic formula. The removal of the external coordinates leads to the values of $n^{(\gamma)}$(vib) shown in the last column. The values of $n^{(\gamma)}$(vib) given for the doubly degenerate species are the number of pairs of normal modes. Thus, for example, there are three pairs of normal modes of symmetry E_u, corresponding to three distinct vibrational frequencies. Note that the subscripts g and u (German: gerade, ungerade) specify the symmetry with respect to the inversion operation, as indicated in Table 4.

Table 4 Character table for the group $_{3d}$ and the analysis of the normal modes of vibration of ethane

$_{3d}$	E	$2C_3$	$3C_2$	i	$2S_6$	$3\sigma_d$		$n^{(\gamma)}$ (tot)	$n^{(\gamma)}$ (vib)
A_{1g}	1	1	1	1	1	1		3	3

A_{1u}	1	1	1	−1	−1	−1		1	1
A_{2u}	1	1	−1	−1	−1	1	T_z	3	2
E_u	2	−1	0	−2	1	0	(T_x,T_y)	4	3
χ_j	24	0	0	0	0	4			

4.8 Symmetry Coordinates

The characters χ_j for the examples in the previous section were calculated with the use of Equation (51), that is, on the basis of Cartesian displacement coordinates. Alternatively, it is often desirable to employ a set of internal coordinates as the basis. However, they must be well chosen so that they are sufficient to describe the vibrational degrees of freedom of the molecule and that they are linearly independent. The latter condition is necessary to avoid the problem of redundancy. Even when properly chosen, the internal coordinates still do not usually transform following the symmetry of the molecule. Once again, the water molecule provides a very simple example of this problem.

The internal coordinates for the water molecule are defined in Figure 3. The effect of each symmetry operation of the symmetry group $_{2v}$ on these internal coordinates is specified in Table 5. Clearly, the internal coordinate $\Delta\alpha$ is totally symmetric, as the characters $\chi_j(\Delta\alpha)$ correspond to those given for the IR A_1. On the other hand, the characters $\chi_j(\Delta r)$, as shown, cannot be identified with a specific IR. By inspection of Table 5, however, it is apparent that the direct sum $A_1 \oplus B_2$ corresponds to the correct symmetry of these coordinates. In more complicated cases the magic formula can always be employed to achieve the correct reduction of the representation in question.

From the above analysis, as shown in the last column of Table 5, it should be obvious that two linear combinations of the internal coordinates Δr can be formed whose symmetry corresponds to the IRs A_1 and B_2. They are $\Delta r_1 + \Delta r_2$ (A_1) and $\Delta r_1 - \Delta r_2$ (B_2), as can be verified by inspection of the character table.

Coordinates such as these, which have the symmetry properties of the point group, are known as symmetry coordinates. As they transform in the same manner as the IRs when used as basis coordinates, they factor the secular determinant into block-diagonal form.[3] Thus, while normal coordinates must be found to diagonalize the secular determinant, the factorization resulting from the use of symmetry coordinates often provides considerable simplification of the vibrational problem. Furthermore, symmetry coordinates can be chosen a priori by a simple analysis of the molecular structure.

Table 5 Symmetry of the internal coordinates for the water molecule

$_{2v}$	E	C_2	$\sigma(zx)$	$\sigma(yz)$	$n^{(\gamma)}(\Delta\alpha)$	$n^{(\gamma)}(\Delta r)$
A_1	1	1	1	1	1	1
A_2	1	1	−1	−1	0	0
B_1	1	−1	1	−1	0	0
B_2	1	−1	−1	1	0	1
$\chi_j(\Delta\alpha)$	1	1	1	1		
$\chi_j(\Delta r)$	2	0	0	2		

In the example considered above, $\Delta r_1 - \Delta r_2$ is the only symmetry coordinate of species B_2. Thus, it results in a factor of degree one in the completely reduced secular determinant. It is therefore a normal coordinate. On the other hand, the two normal coordinates of species A_1 are linear combinations of the symmetry coordinates $\Delta\alpha$ and $\Delta r_1 + \Delta r_2$. They can only be found by solution of the secular equations.

It is usually convenient to normalize the symmetry coordinates. Hence, for the example considered here, the three symmetry coordinates take the form (Equation 56)

$$\text{species } A_1: \quad \begin{aligned} \mathsf{S}_1 &= \Delta\alpha \\ \mathsf{S}_2 &= \tfrac{1}{\sqrt{2}}(\Delta r_1 + \Delta r_2) \end{aligned} \tag{56}$$

and (Equation 57)

$$\text{species } B_2: \mathsf{S}_3 = \tfrac{1}{\sqrt{2}}(\Delta r_1 - \Delta r_2) \tag{57}$$

where the normalizing factor $_p$ is determined by the condition (Equation 58)

$$_p{}^2 \sum_t \mathsf{S}_t^2 = 1 \tag{58}$$

for each symmetry coordinate S_p. In general form, the relations given by Equations (56) and (57) are expressed by the matrix relation (Equation 59)

$$\mathsf{S} = \boldsymbol{U}\boldsymbol{S} \tag{59}$$

which for the above example becomes (Equation 60)

$$\begin{pmatrix} \mathsf{S}_1 \\ \mathsf{S}_2 \\ \mathsf{S}_3 \end{pmatrix} = \begin{matrix} 0 & 0 & 1 \\ \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} & 0 \\ \frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} & 0 \end{matrix} \begin{pmatrix} \Delta r_1 \\ \Delta r_2 \\ \Delta\alpha \end{pmatrix} \tag{60}$$

It should be noted that when the symmetry coordinates have been normalized, $\boldsymbol{U}$ is orthogonal, that is, $\boldsymbol{U} = \boldsymbol{U}^{-1}$. The matrices $\boldsymbol{U}$ can be constructed with the use of projection operators. For lack of space, this method will not be presented here.

To show how use is made of symmetry coordinates as the bases of the vibrational problem, reconsider the kinetic and potential energies as given earlier, e.g. (Equation 61)

$$2T = \dot{\boldsymbol{S}}\boldsymbol{G}^{-1}\boldsymbol{S} = \dot{\boldsymbol{Q}}\boldsymbol{E}\dot{\boldsymbol{Q}} \tag{61}$$

and (Equation 62)

$$2V = \boldsymbol{S}\boldsymbol{F}\boldsymbol{S} = \boldsymbol{Q}\boldsymbol{\Lambda}\boldsymbol{Q} \tag{62}$$

From Equation (59), we have (Equation 63)

$$\boldsymbol{S} = \boldsymbol{U}^{-1}\mathsf{S} = \boldsymbol{U}\mathsf{S} \tag{63}$$

hence (Equation 64)

$$2T = \dot{\mathsf{S}}\mathsf{G}^{-1}\dot{\mathsf{S}} = \dot{\boldsymbol{Q}}\boldsymbol{E}\dot{\boldsymbol{Q}} \tag{64}$$

and (Equation 65)

$$2V = \mathsf{SFS} = \boldsymbol{Q}\boldsymbol{\Lambda}\boldsymbol{Q} \tag{65}$$

In Equations (64) and (65) the definitions $\mathsf{G} \equiv \boldsymbol{UGU}$ and $\mathsf{F} \equiv \boldsymbol{UFU}$ have been introduced. These equations lead to the secular determinant as before (Equation 66):

$$|\mathsf{GF} - \boldsymbol{E}\lambda_k| = 0 \tag{66}$$

The eigenvectors L with this basis can be found from $\mathsf{L} = \boldsymbol{UL}$.

Returning now to the example of the water molecule, with $\boldsymbol{F}$ given by Equation (35) and $\boldsymbol{U}$ in Equation (60), the transformation $\boldsymbol{UFU}$ gives Equation (67):

$$\mathsf{F} = \left[\begin{array}{cc:c} f_\alpha & \sqrt{2}f_{r\alpha} & 0 \\ \sqrt{2}f_{r\alpha} & f_r + f_{rr} & 0 \\ \hdashline 0 & 0 & f_r - f_{rr} \end{array}\right] \tag{67}$$

Similarly, $\boldsymbol{UGU}$ leads to Equation (68):

$$\mathsf{G} = \left[\begin{array}{cc:c} 2\mu_H/r^2 + 2\mu_O \times\dfrac{(1-\cos\alpha)}{r^2} & -\dfrac{\sqrt{2}\mu_O \sin\alpha}{r} & 0 \\ -\dfrac{\sqrt{2}\mu_O \sin\alpha}{r} & \mu_H + \mu_O \times(1+\cos\alpha) & 0 \\ \hdashline 0 & 0 & \mu_H + \mu_O \times(1-\cos\alpha) \end{array}\right] \tag{68}$$

As both F and G are partitioned by the use of symmetry coordinates, the secular determinant is factored accordingly. The problem of calculating the vibrational frequencies is thus divided into two parts: solution of a linear equation for the single frequency of species B_2 and of a quadratic equation for the pair of frequencies of species A_1.

On the other hand, it is often of interest to calculate force constants from observed vibrational frequencies. However, it is not generally possible to derive analytical expressions for the force constants as functions of the frequencies and the molecular geometry. The calculation is necessarily an iterative one. Starting with a set of assumed force constants – usually obtained by analogy with similar bonds in other molecules – the values are refined until a suitable set is found. The set that yields the best agreement between calculated and observed frequencies constitutes the accepted force field for the molecule.

From the above example, it is apparent that there may be (and usually are) more unknown force constants than observed frequencies. If no additional sources of data are available, it is necessary to make some assumptions to simplify the force field. Often some or all of the off-diagonal elements in the $\boldsymbol{F}$ matrix (Equation 23) are neglected, leading to the so-called VFF or modified valence force field (MVFF), respectively.

Assuming that a reasonable force field is known, the solution of the above equations to obtain the vibrational frequencies of water is not difficult. However, in more complicated molecules it very rapidly becomes a formidable one. If there are N atoms in the molecule, there are $3N$ total degrees of freedom and $3N - 6$ for the vibrational frequencies. The molecular symmetry can often aid in simplifying the calculations, although in large molecules there may be no true symmetry. In some cases the notion of local symmetry can be introduced to simplify the calculation of vibrational frequencies and the corresponding forms of the normal modes of vibration.

Regardless of the force field chosen, the calculation of vibrational frequencies by the method outlined above is based on the harmonic approximation. Tabulated values of force constants can be used to calculate vibrational frequencies, for example, of molecules whose vibrational spectra have not been observed. However, as anharmonicities have been neglected in the above analysis, the resulting frequency values are often no better than ±5% with respect to those observed.

For the example of the water molecule, it is of interest to calculate the forms of the vibrational modes, as obtained from the evaluation of the matrix $\mathsf{L} = \boldsymbol{UL}$. The results can be presented most simply in the form shown in Figure 8. The calculation of the specific form of the normal modes is relatively complicated, although with the aid of current computer programs it becomes routine – at least for relatively simple molecules.

It is apparent from Figure 8 that the normal modes of vibration of the water molecule, as calculated from the eigenvectors, can be described approximately as a symmetrical stretching vibration (ν_1) and a symmetrical bending vibration (ν_2). It should be emphasized that the two normal modes of species A_1 are linear combinations of the two internal symmetry coordinates given by Equations (56) and (57). On the other hand, as there is only one symmetry coordinate of species B_2 in this

Figure 8 The normal modes of vibration of the water molecule.

case, it is identical with the normal coordinate shown for ν_3 and can be correctly described as an antisymmetric stretching vibration.

It has been shown that the potential energy distribution provides an approximate method to evaluate the relative contribution of each symmetry coordinate to a given normal mode of vibration. From the definition of the symmetry coordinates (Equation 59), the relation (Equation 69)

$$\mathsf{LFL} = \Lambda \tag{69}$$

or (Equation 70)

$$\sum_{pp'} \mathsf{L}_{pk}\mathsf{L}_{p'k}\mathsf{F}_{pp'} = \lambda_k \quad k = 1, 2, \ldots, 3N-6 \tag{70}$$

can be derived. As the diagonal elements of F are usually at least an order of magnitude greater than the off-diagonal elements, the relation (Equation 71)

$$\frac{1}{\lambda_k}\sum_{p} \mathsf{L}_{pk}^2\mathsf{F}_{pp} \approx 1 \quad k = 1, 2, \ldots, 3N-6 \tag{71}$$

is approximately equivalent to Equation (70). Each term on the left-hand side of Equation (71) represents the approximate contribution of each symmetry coordinate S_p to the normal coordinate Q_k. The evaluation of this potential-energy distribution, and also the form of the normal vibrations, is usually carried out by current computer programs for the calculation of vibrational frequencies.

4.9 Characteristic Group Frequencies

Organic chemists are familiar with the use of infrared spectroscopy to identify functional groups in an unknown compound.[7] This method of qualitative analysis is possible because the infrared absorption bands of many common functional groups vary but little from one molecule to another. For example, the band assigned to the carbonyl group, C=O, in ketones is usually found in the range $1710 - 1720\,\mathrm{cm}^{-1}$. Similarly, in aldehydes it is between 1715 and $1735\,\mathrm{cm}^{-1}$ and in organic acids from 1750 to $1770\,\mathrm{cm}^{-1}$. The assignment of these bands to the carbonyl group implies that the normal modes of vibration corresponding to the observed frequencies are localized, that is, they involve only (or at least primarily) the internal coordinate that is the variation in the length of the C=O bond. Such assignments, which have been established empirically, are very useful, although they should be applied with caution. In this particular case the vibrational frequency associated with the carbonyl group is characteristic because the force constant of the carbon–oxygen double bond has approximately twice the value of the nearby single bonds. Substitution on an adjacent carbon atom will, however, produce frequency shifts, as indicated above.

From a theoretical point of view, if the matrices $\boldsymbol{G}$ and $\boldsymbol{F}$ are expressed in internal coordinates, the vibrational frequencies are determined from the eigenvalues of their product (Equation 31). In the case of a carbonyl compound, the change in the C=O distance could be chosen as the internal coordinate associated with the element $(\boldsymbol{GF})_{11}$. In the limit as either off-diagonal element $(\boldsymbol{GF})_{12}$ or $(\boldsymbol{GF})_{21}$ is much smaller than the diagonal element $(\boldsymbol{GF})_{11}$, the chosen internal coordinate becomes a normal coordinate, that is, it is ''uncoupled'' from the rest of the molecule. The normal coordinate is then localized and the observed frequency can be correctly described as a carbonyl vibration.

A more complicated example of characteristic group frequencies can be illustrated by consideration of the methyl group, CH_3, as shown in Figure 9. It is assumed in this model that the methyl group is attached to the molecular framework, represented here by an infinite mass. If the symmetry of the methyl group is not modified by the presence of the molecular framework, the point group is $_{3v}$ and the analysis can be carried out as illustrated in section 4.8. The results are summarized in Table 6, where the figures given in the last line were calculated with the use of Equation (51). Application of the magic formula yields the reduced representation for the $3N = 15$ degrees of freedom of the methyl group attached to the mass X. Removal of the external coordinates leads to the result shown in the last column for the vibrational degrees of freedom, $3A_1 \oplus 3E$.

The 10 internal coordinates for the attached methyl group can be combined to form the symmetry coordinates

Figure 9 The methyl group attached to an infinite mass X.

Table 6 The character table for the point group $_{3v}$ and the analysis of the methyl group

$_{3v}$	E	$2C_3$	$3\sigma_v$		$n^{(\gamma)}$ (tot)	$n^{(\gamma)}$ (vib)
A_1	1	1	1	T_z	4	3
A_2	1	1	−1	R_z	1	0
E	2	−1	0	(T_x, T_y) (R_x, R_y)	5	3
χ_j	15	0	3			

given by Equation (72):

$$\text{species } A_1: \quad \begin{aligned} \mathsf{S}_1 &= \tfrac{1}{\sqrt{3}}(\Delta r_1 + \Delta r_2 + \Delta r_3) \\ \mathsf{S}_2 &= \tfrac{1}{\sqrt{6}}(\Delta\alpha_{23} + \Delta\alpha_{31} + \Delta\alpha_{12} \\ &\quad - \Delta\beta_1 - \Delta\beta_2 - \Delta\beta_3) \\ \mathsf{S}_3 &= \Delta R \end{aligned} \tag{72}$$

and Equation (73):

$$\text{species } E: \quad \begin{aligned} \mathsf{S}_{4a} &= \tfrac{1}{\sqrt{6}}(2\Delta r_1 - \Delta r_2 - \Delta r_3) \\ \mathsf{S}_{5a} &= \tfrac{1}{\sqrt{6}}(2\Delta\alpha_{23} - \Delta\alpha_{31} - \Delta\alpha_{12}) \\ \mathsf{S}_{6a} &= \tfrac{1}{\sqrt{6}}(2\Delta\beta_1 - \Delta\beta_2 - \Delta\beta_3) \\ \mathsf{S}_{4b} &= \tfrac{1}{\sqrt{2}}(\Delta r_2 - \Delta r_3) \\ \mathsf{S}_{5b} &= \tfrac{1}{\sqrt{2}}(\Delta\alpha_{31} - \Delta\alpha_{12}) \\ \mathsf{S}_{6b} &= \tfrac{1}{\sqrt{2}}(\Delta\beta_2 - \Delta\beta_3) \end{aligned} \tag{73}$$

It is then apparent that the three normal modes of vibration of species A_1 are linear combinations of the three symmetry coordinates given by Equation (72). The three frequencies corresponding to these three normal modes are by convention designated by ν_1, ν_2 and ν_3. The symmetry coordinates of species E given by Equation (73) consist of three pairs, identified by the subscripts a and b. The coordinates labeled a are symmetric with respect to the plane defined by H_1, C and X, while the three labeled b are antisymmetric. Appropriate linear combinations of the three members of each pair are the normal coordinates of this species. Either set of three symmetry coordinates, when substituted into the secular determinant, yields the corresponding vibrational wavenumbers of the modes ν_4, ν_5 and ν_6. Representative results are summarized in Table 7.

The fourth column in Table 7 presents an evaluation of the contribution of each symmetry coordinate to a given normal mode of vibration of the methyl group. It is obvious that the often-used descriptions, as given in the last column of Table 7, are only approximate. It should be noted that the quantitative evaluation of the contribution of each symmetry coordinate to a given normal mode can be estimated by the calculation of the potential energy distribution (see Equation 71).

Table 7 The normal modes of vibration of an isolated methyl group

Mode	Species	Wavenumber (cm^{-1})	Symmetry coordinates	Approx. description
ν_1	A_1	2880	S_1 (100%)	Sym. CH stretch
ν_2	A_1	1250–1400[a]	S_2 (~80%)	Sym. CH bend
ν_3	A_1	~530[a]	S_3 (60–80%), S_2 (~30%)	CX stretch
ν_4	E	2960	S_4 (100)%	Antisym. CH stretch
ν_5	E	1450	S_5 (~80%), S_6 (~20%)	Antisym. CH bend
ν_6	E	960	S_6 (80%), S_5 (~20%)	CH_3 rocking

[a] The wavenumber of these modes, and also the relative contributions of the different symmetry coordinates, are very sensitive to the value of the force constant for the CX bond.

4.10 Spectroscopic Selection Rules

The relation between classical and quantum mechanics was pointed out in section 2.2. There it was shown that the difference between successive energy levels for the harmonic oscillator in quantum mechanics, when divided by Planck's constant, yields the value of the vibrational frequency of the equivalent classical oscillator. This result is an example of the correspondence principle. In the preceding section the vibration of polyatomic molecules is treated in a purely classical manner. With the use of normal modes the molecular vibrations become separated, each possessing a characteristic vibrational frequency. It then becomes possible to consider each normal mode as a quantum-mechanical oscillator, thanks to the correspondence principle. This fact is of extreme importance in vibrational spectroscopy, as it permits the calculation of the harmonic frequencies of vibration of the molecules with the use of the methods of classical mechanics (see section 3.5). The extension of the model to include the anharmonicity provides a basis for the qualitative interpretation of observed overtones and combinations of the fundamental vibrational frequencies.

In absorption spectroscopy the electric vector $\boldsymbol{\mathcal{E}}$ of the incident radiation couples with the electric dipole moment $\mathbf{m}$ of the molecular system. The resulting time-dependent perturbation of the Hamiltonian (Equation 74),

$$\boldsymbol{H}' = -\mathbf{m} \cdot \boldsymbol{\mathcal{E}} \tag{74}$$

induces a transition in the molecule and a corresponding absorption of energy. The probability per second of the transition from the state n to the state m is given by the Einstein coefficient for absorption, which can be written in the following form (Equation 75):

$$B_{n\to m} = \frac{8\pi^3}{3h^2} \; \langle m|\mathrm{m}_X|n\rangle^2 + \langle m|\mathrm{m}_Y|n\rangle^2 + \langle m|\mathrm{m}_Z|n\rangle^2 \tag{75}$$

This result is obtained by application of time-dependent perturbation theory.[6] It also applies to the processes of spontaneous and induced emission. It should be noted that the factor before the brackets on the right-hand side of Equation (75) depends on the units employed and is unimportant for the purposes of this article.

In Equation (75) the notation of Dirac has been used to represent the appropriate integrals. Thus, for example (Equation 76),

$$\langle m|\mathrm{m}_X|n\rangle = \int \psi_m^* \mathrm{m}_X \psi_n \, \mathrm{d}\tau \tag{76}$$

where ψ_n and ψ_m are the wave functions for the initial and final states, respectively, and $\mathrm{d}\tau$ represents the volume element in the space in question. For readers familiar with quantum mechanics it is apparent that when $n = m$, Equation (76) expresses the average value of the x-component of the dipole moment of the molecule in that state. However, when $n \neq m$ the integral in Equation (76) is known as the transition moment for this component. This, and the two analogous terms in Equation (75), determine the selection rules for this transition. Clearly, if all three transition moments are equal to zero, the transition cannot take place – it is said to be forbidden. The vanishing (or nonvanishing) of an integral of this type can be established by consideration of the symmetry of the integrand. It is here again that group theory, as outlined in section 4.2, plays an important role.[5]

In the rigid-rotator approximation, the energy was written as the sum given by Equation (11). To the same degree of approximation the wave function for a free molecule is simply the product in Equation (77):

$$\psi \approx \psi(\mathrm{rot})\psi(\mathrm{vib}) \tag{77}$$

The dipole moment in Equation (74) has been expressed in space-fixed coordinates X, Y, Z in the equations that follow. However, it is necessary to establish a Cartesian coordinate system x, y, z attached to the molecule and related to the space-fixed system by Equation (78):

$$\mathbf{m}(X, Y, Z) = \mathbf{\Phi}\mathbf{m}(x, y, z) \tag{78}$$

where $\mathbf{\Phi}$ is a three-by-three matrix whose elements are direction cosines connecting the various pairs of axes.[4] With the use of Equations (77) and (78) the transition moment for the component m_X becomes (Equation 79)

$$\begin{aligned}
\langle m|\mathrm{m}_X|n\rangle = {} & \int \psi_m^*(\mathrm{rot})\Phi_{Xx}\psi_n(\mathrm{rot})\,\mathrm{d}\tau_{\mathrm{rot}} \\
& \times \int \psi_m^*(\mathrm{vib})\mathrm{m}_x\psi_n(\mathrm{vib})\,\mathrm{d}\tau_{\mathrm{vib}} \\
& + \int \psi_m^*(\mathrm{rot})\Phi_{Xy}\psi_n(\mathrm{rot})\,\mathrm{d}\tau_{\mathrm{rot}} \\
& \times \int \psi_m^*(\mathrm{vib})\mathrm{m}_y\psi_n(\mathrm{vib})\,\mathrm{d}\tau_{\mathrm{vib}} \\
& + \int \psi_m^*(\mathrm{rot})\Phi_{Xz}\psi_n(\mathrm{rot})\,\mathrm{d}\tau_{\mathrm{rot}} \\
& \times \int \psi_m^*(\mathrm{vib})\mathrm{m}_z\psi_n(\mathrm{vib})\,\mathrm{d}\tau_{\mathrm{vib}}
\end{aligned} \tag{79}$$

To separate completely the integrals over rotational and vibrational coordinates, each component of the dipole moment is expanded about the equilibrium configuration in a Taylor's series in normal coordinates. That is (Equation 80),

$$\mathrm{m}_x = \mathrm{m}_x^0 + \sum_{k=1}^{3N-6} \left(\frac{\partial \mathrm{m}_x}{\partial Q_k}\right)_0 Q_k + \cdots \tag{80}$$

and similarly for the other components. The higher terms in Equation (80), which account for the so-called electrical anharmonicity, are almost invariably neglected. Expressions of the form of Equation (80) for the various components are substituted into the three equations for the matrix elements, Equation (79) being one of them. Then, for example, the first term of Equation (79) becomes (Equation 81)

$$\begin{aligned}
\langle m|\mathrm{m}_{Xx}|n\rangle = {} & \mathrm{m}_x^0 \int \psi_m^*(\mathrm{rot})\Phi_{Xx}\psi_n(\mathrm{rot})\,\mathrm{d}\tau_{\mathrm{rot}} \\
& + \sum_{k=1}^{3N-6} \left(\frac{\partial \mathrm{m}_x}{\partial Q_k}\right)_0 \int \psi_m^*(\mathrm{vib})Q_k\psi_n(\mathrm{vib})\,\mathrm{d}\tau_{\mathrm{vib}} \\
& \times \int \psi_m^*(\mathrm{rot})\Phi_{Xx}\psi_n(\mathrm{rot})\,\mathrm{d}\tau_{\mathrm{rot}}
\end{aligned} \tag{81}$$

where the integral over the vibrational coordinates normalizes to unity in the first term. Evaluation of integrals such as the first of Equation (81) results in the rotational selection rules that govern pure-rotational transitions in the microwave and far-infrared spectra of gases. These transitions involve no change in the vibrational state of the molecule.

The second term in Equation (81) contains the product of two integrals, one over rotational coordinates and the other over vibrational coordinates. Therefore, the nonvanishing of this term places simultaneous restrictions on changes of rotational and vibrational states. It is the origin of the selection rules for rotation–vibration absorption bands in the infrared spectral region. The evaluation of the integrals over rotational coordinates depends on the type of rotator involved, being relatively straightforward for linear or symmetric tops (see section 3.8).

The integrals over the vibrational coordinates in Equation (81) can be easily calculated in the harmonic approximation. In this case the properties of the Hermite polynomials yield directly the vibrational selection rule $\Delta v_k = \pm 1$, where v_k is the vibrational quantum number for the kth normal mode. As most molecules are in their vibrational ground state ($v_k = 0$ for all values of k) at ordinary temperatures, the most important features in the absorption spectrum of a molecule are those corresponding to the transitions $v_k = 0 \Rightarrow v_k = 1$ for a given k. This process is the absorption of but a single

quantum of vibrational energy. The absorption band observed in the infrared region is then referred to as a vibrational fundamental.

The selection rule given above, $\Delta v_k = \pm 1$, applies in the harmonic approximation; it will break down when anharmonicity is important. The effect of anharmonicity is (i) to modify the regular spacing of energy levels and (ii) to relax the harmonic selection rule. Thus, in the spectra of real molecules, absorption features are often observed at frequencies of approximately $2\nu_k$, $3\nu_k$, etc. the overtones, and at approximately $\ell\nu_k \pm \ell'\nu_k(\ell, \ell' = 1, 2, \ldots)$, the combinations. The quantitative analysis of these effects requires the addition of anharmonic terms in the potential energy. They have been neglected in treatments of all but the simplest (triatomic) polyatomic molecules.

4.11 Symmetry and Selection Rules

The vanishing (or nonvanishing) of an integral such as those given in Equation (79) can be determined by consideration of the symmetry properties of the integrand. It is sufficient to recall that in elementary calculus the symmetry (odd or even) of a function determines the value of its integral between symmetric limits. The same principle can be generalized and applied to the present problem. Thus, the symmetry properties of an integral such as Equation (82)

$$\psi_m^*(\text{vib})\text{m}_x\psi_n(\text{vib})\,\text{d}\tau_{\text{vib}} \tag{82}$$

can be established by consideration of the symmetry of each factor in the integrand. This approach to the problem is general, although in certain cases, particularly when degenerate wavefunctions are involved, it can be complicated. The interested reader is referred to the book by Wilson, Decius and Cross for the analysis of this problem.[3]

In its simplest form, as the IR of each factor in the integrand of Equation (82) can be established with reference to the symmetry group of the molecule, the overall symmetry of the integrand can be determined. If the IR for each factor has been found, their direct product describes the resulting symmetry. This representation, which can then be reduced, viz. (Equation 83)

$$\mathbf{\Gamma}^{(\gamma'')} \otimes \mathbf{\Gamma}^{(\gamma')} \otimes \mathbf{\Gamma}^{(\gamma)} = \sum_{\ell} n^{(\ell)}\mathbf{\Gamma}^{(\ell)} \tag{83}$$

is used to determine the selection rule for any transition $n \Rightarrow m$. In Equation (83), $\mathbf{\Gamma}^{(\gamma)}$ and $\mathbf{\Gamma}^{(\gamma'')}$ are the IRs of the initial and final states, respectively, while in this example the x-component of the dipole moment belongs to the IR $\mathbf{\Gamma}^{(\gamma)}$. The general rule follows. If the reduced representation, as given by the right-hand side of Equation (83) does not contain the totally symmetric IR, $\Gamma^{(1)}$, the integral given by Equation (82), is equal to zero. The transition $n \Rightarrow m$ involving the x-component of the dipole moment is then forbidden. It should be noted that the initial state n is not necessarily the ground state of the molecule.

As an illustration of the analysis outlined in the preceding paragraph, consider a fundamental absorption band of the ethane molecule. The symmetry of this molecule, which was described in section 4.7, leads to the character table given as Table 4. The structure of the reduced representation is then established with the use of the magic formula. These results are shown in the last two columns of Table 4. For fundamental transitions, those which originate from the (always) totally symmetric ground state of the molecule, their symmetry is thus described by $\mathbf{\Gamma}^{(\gamma)} = \mathbf{\Gamma}^{(1)}$. From Table 4 it is apparent that there are two normal modes of symmetry A_{2u}. The symmetry of the dipole moment of the molecule is characterized by the components T_z, of symmetry A_{2u}, and the pair of components (T_x, T_y), of symmetry E_u.

If, for example, a fundamental transition such as $A_{1g} \Rightarrow A_{2u}$ is considered, Equation (81) becomes Equation (84):

$$A_{1g} \otimes A_{2u} \otimes A_{2u} = A_{1g} \tag{84}$$

as can be easily established by multiplying the characters given in Table 4. Here it has been assumed that it is the z-component of the dipole moment that plays an active role in the transition. For this example, then, these fundamental transitions are allowed, as the right-hand side of Equation (84) contains the totally symmetric IR, A_{1g}.

For the three vibrational fundamentals of species E_u, only the x, y coordinates of the dipole moment can provide infrared activity. This result is apparent from Equation (85):

$$A_{1g} \otimes E_u \otimes E_u = A_{1g} \oplus A_{2g} \oplus E_g \tag{85}$$

which is established by taking the appropriate products of the characters given in Table 4 and making the reduction of the representation with the use of the magic formula. As Equation (85) contains the totally symmetric representation A_{1g}, these vibrational fundamentals of ethane are active in its infrared spectrum. The other normal modes of this molecule, as summarized in the right-hand column of Table 4, cannot be infrared active.

The symmetry arguments presented in the preceding two paragraphs are general. They apply not only to the vibrational fundamentals, but also to the overtones and combinations. However, for the vibrational fundamentals they lead to a very simple rule, namely that for a normal mode to produce a fundamental transition it must belong to an IR which also contains a component of the

dipole moment. The more general method of analysis, as described above, is presented in more detail in a number of advanced texts.[3,6,8]

4.12 Absorption Intensities

From the above discussion, it is apparent that the possibility of absorption of radiation by a molecule depends on its dipole moment in the case of pure-rotational spectra and on its dipole moment derivatives for vibrational spectra. Hence it is not surprising that the observed intensities of absorption lines or bands can be used as quantitative measures of the molecular dipole moment and its derivatives.

If a beam of light of intensity falls on a layer of sample material of infinitesimal thickness $d\ell$, the decrease in intensity of the beam is given by Lambert's law (Equation 86):

$$-d \quad = a \quad d\ell \tag{86}$$

where a is the absorption coefficient. This expression can be integrated to yield

$$\ln \frac{}{0} = -a\ell \tag{87}$$

where ℓ is the thickness of the sample and $_0$ is the intensity of the radiation incident on it. As the absorption coefficient, a, is proportional to $N_n B_{n\Rightarrow m}$, light absorption depends on the number of molecules present in the initial state of the system, in addition to the nonvanishing of the Einstein coefficient. The former condition is, of course, the origin of Beer's law, the basis of the application of absorption spectroscopy in quantitative analysis. It is important to note that from a theoretical point of view, the absorption coefficient is proportional to the area of a given absorption band and not necessarily to its peak height. This question will be treated in section 6 in connection with the analysis of band shapes.

5 SPECTRA OF GASES AND VAPORS

The rotational transitions which accompany a given vibrational transition in a polyatomic molecule produce a rotational structure on the infrared absorption band. For molecules with relatively large moments of inertia, this structure is often not observed, particularly at relatively low spectral resolution. However, small molecules in the gaseous phase yield spectra with easily resolved fine structure that can provide considerable information.[9]

5.1 Diatomic and Linear Molecules

The energy of a rotating, vibrating diatomic molecule was considered in section 2.3. There it was shown that its energy is given by Equation (12), at least in the rigid-rotor approximation. This model was then generalized to take into account vibrational anharmonicity, rotation–vibration coupling and centrifugal distortion (Equation 13).

Figure 10 The fundamental rotation–vibration spectrum of gaseous HCl.

The fundamental rotation–vibration band of HCl is presented in Figure 10 as an example. The series of lines on the low-frequency side constitute the P branch, which arises from the selection rule $\Delta J = -1$. The analogous features on the high-frequency side form the R branch ($\Delta J = +1$). This spectrum was obtained under medium resolution. However, it is sufficient to show that each "line" in the rotational fine structure is in fact a doublet. This splitting of each line is due to the isotope effect. Specifically, the observed spectrum can be considered to be the superposition of two spectra, those of $H^{35}Cl$ and $H^{37}Cl$. Those rotational lines that are at lower frequencies are due to the isotopic species with the higher moment of inertia. The relative intensities of the two series of lines is a direct measure of the isotopic ratio for the chlorine atom in natural abundance. The gap in the middle of the spectrum is a manifestation of the selection rules, for which $\Delta J = 0$ is forbidden.

Those polyatomic molecules for which, in the equilibrium configuration, all of the atoms lie along a straight line, can be analyzed similarly. In this case there are $3N - 5$ normal modes of vibration, each with a wavenumber $\bar{\nu}_k$. The vibrational energy is given by Equation (88):

$$\frac{E_{\text{vib}}}{hc} = \sum_{k=1}^{3N-5} \bar{\nu}_k \left(v_k + \frac{1}{2} \right. \tag{88}$$

in the harmonic approximation, where $v_k = 0, 1, \ldots, 3N - 5$. However, in the case of degeneracy, in which two modes have the same frequency, two identical terms in Equation (88) will be obtained. Thus, it is convenient to rewrite this equation in the following form (Equation 89):

$$\frac{E_{\text{vib}}}{hc} = \sum_{i} \bar{\nu}_i \left(v_i + \frac{d_i}{2} \right. \tag{89}$$

where the summation is now over all wavenumbers and the degree of degeneracy of each mode is equal to d_i.

The addition of the rotational contribution to the energy, as given by the second term on the right-hand side of Equation (12), to Equation (89) leads to Equation (90):

$$\frac{E_{\text{vib}} + E_{\text{rot}}}{hc} = \sum_i \overline{\nu}_i \left(v_i + \frac{d_i}{2} \right) + \overline{B}_e J(J+1) \quad (90)$$

in the rigid-rotor, harmonic oscillator approximation. Once again, this result can be generalized to include the effects of anharmonicity, centrifugal distortion and rotation–vibration coupling. It should be noted that consideration of the anharmonicity will introduce cross-terms between the various modes, which, strictly, are no longer normal modes of vibration. Furthermore, a relatively more important contribution to rotation–vibration coupling arises in this case from Coriolis forces for which a term must be added to take into account the angular momentum around the molecular axis. This term, which enters for modes involving bending of the molecule, requires the definition of an additional quantum number, $\ell = 1, 2, \ldots$. In the case of bending modes the condition imposed on this quantum number, $J = \ell, \ell + 1, \ell + 2 \ldots$, results in certain missing rotational lines and in splitting of others (ℓ doubling) due to the removal of the twofold degeneracy. While these effects are essential in the quantitative analysis of the rotation–vibration spectra of small molecules, they become less important as the moment of inertia increases (and hence the value of $\overline{B}_e$ decreases).

As a first approximation, the rotation–vibration spectrum of a linear molecule can be interpreted on the basis of Equation (90). However, the appropriate selection rules must be applied. In the case of a diatomic molecule the selection rule $\Delta J = \pm 1$ was used because the change in dipole moment is of course along the molecular axis. The same rule applies for linear polyatomic molecules when the dipole moment derivative is similarly directed. However, for vibrational fundamentals arising from bending vibrations of linear molecules, the dipole moment variation is oriented perpendicular to the molecular axis. The selection rule in this case is $\Delta J = 0, \pm 1$. Reference to Figure 2 then shows that the transitions of the type $\Delta J = 0$ will result in a series of lines at approximately the same wavenumber. These features constitute the Q branch in the rotation–vibration spectrum.

It is of interest to regard the infrared spectra of a simple linear molecule on the basis of the general theory presented above. As an example, consider the carbon dioxide molecule, whose equilibrium configuration is described by the point group $_{\infty}$h. The three fundamental vibrations of this molecule are represented in Figure 11. It should be noted that ν_2 is doubly degenerate, leading to

Figure 11 The normal modes of vibration of the carbon dioxide molecule. The IRs in point group $_{\infty}$h are shown on the right.

Figure 12 Portions of the infrared spectrum of carbon dioxide gas: the ν_3 fundamental.

a nonzero angular momentum about the molecular axis and the symbol Π for the IR. Only the two vibrational fundamentals ν_3 and ν_2 are infrared-active.

The infrared spectrum of carbon dioxide in the region of its vibrational fundamental ν_3 is shown in Figure 12. This band, which arises from the asymmetric stretching vibration, displays the characteristic P–R branches, analogous to those in the spectrum of a diatomic molecule. Furthermore, the intensity distribution of these branches is similar as illustrated in Figure 10 for hydrogen chloride. A weak, alternating variation in the intensities of the individual lines can be detected in Figure 12. This intensity pattern is due to the effect of the spins of the nuclei that are interchanged under the inversion operation.[9]

The ν_2 fundamental absorption band of carbon dioxide is presented in Figure 13. It is characterized by an intense Q branch, which arises from the series of lines due to the $\Delta J = 0$ transitions. These lines are not superimposed because the moments of inertia of the molecule are not exactly the same in the fundamental and first excited vibrational states. Under high resolution these lines can be clearly resolved in this case. The P and R branches

Figure 13 Portions of the infrared spectrum of carbon dioxide gas: the ν_2 fundamental.

in Figure 13 also display the characteristic intensity distribution. The detailed analysis of a perpendicular band such as this one requires inclusion of the effect of Coriolis forces, as the angular momentum about the molecular axis is not equal to zero ($\ell = 1$).

From this brief summary of the infrared spectra of linear molecules, it is seen that the vibrations can be classified as stretching or bending modes. The former give rise to parallel bands, while the latter are characterized by perpendicular bands. These descriptions refer to the direction of the dipole moment variation with respect to the molecular axis. The most obvious difference between parallel and perpendicular bands is in the absence or presence, respectively, of the Q branch. Although for larger molecules in the gas phase the rotational structure of absorption bands may not be resolvable, the observed band envelopes often allow parallel and perpendicular bands to be distinguished.

5.2 Spherical Rotators

The term ''spherical top'' is employed to describe a molecule for which, in its equilibrium configuration, all three moments of inertia are equal (see section 3.8). Then, as for linear molecules, the energy in the rigid-rotator approximation is given by Equation (43). However, it should be noted that the degeneracy of the rotational levels becomes equal to $(2J + 1)^2$. This result has an effect on the intensity distribution of a given branch, or its envelope, of an absorption band.

Most molecules in this class whose rotation–vibration spectra have been studied have tetrahedral symmetry. Thus, from the character table for point group T_d it is seen that infrared activity is limited to triply degenerate vibrations of species F_2. As the selection rules appropriate to the F_2 fundamentals are $\Delta J = 0, \pm 1$, rotation–vibration bands with a simple P–Q–R branch structure are predicted. However, as the vibrational levels are degenerate in this case, the effect of Coriolis interaction can become important. This contribution to rotation–vibration interaction results in splitting of the triply degenerate levels into three distinct energies.

Figure 14 The ν_4 fundamental in the infrared spectrum of methane.

The magnitude of the Coriolis splitting varies considerably from one band to another. This fact is exemplified in Figure 14, where the spectrum of the ν_4 fundamental of methane is presented. Although the ν_3 band exhibits the expected simple structure, the ν_4 band is seriously perturbed as a result of interaction with the nearby infrared-inactive vibration ν_2.

From the above example of the infrared spectrum of a spherical rotator, it should be obvious that a complete, quantitative analysis of the rotation–vibration spectrum is not straightforward. Although the broad features of a vibrational fundamental of a molecule in this class are similar to those of a linear molecule, Coriolis interaction often complicates the interpretation.

5.3 Symmetric Rotators

In Equation (45) for the rotational energy of a rigid symmetric top, (Equation 91)

$$\frac{E_{\text{rot}}}{hc} = \overline{B}J(J+1) + (\overline{C} - \overline{B})K^2 \qquad (91)$$

where the rotational constants expressed in wavenumbers are defined with respect to the principal axes. Note that in this case the c-axis has been chosen as the axis of symmetry; thus, $\overline{A} = \overline{B} \neq \overline{C}$. In Equation (91), the rotational quantum numbers are defined as before, namely, $J = 0, 1, 2, \ldots$ and $K = 0, \pm 1, \pm 2, \ldots, \pm J$. If the rotator is an oblate spheroid, $\overline{C} < \overline{B}$ and the second term in Equation (91) is negative. For the prolate top this

term is positive (if the a-axis is chosen to be the unique one, the axis of symmetry, $\overline{B} = \overline{C}$ and the rotational constant $\overline{C}$ is replaced by $\overline{A}$ in Equation 91). As in this approximation the energy depends on K^2, each level for $|K| > 0$ is doubly degenerate. The sign, for a given value of K, represents classically the direction of rotation of the angular momentum about the symmetry axis. Finally, it is apparent that if $\overline{B} = \overline{C}$, Equation (91) reduces to the spherical-top expression.

As a first approximation the energy of a symmetric-top molecule can be written as the sum of those of a rigid rotor and $3N - 6$ harmonic oscillators. However, in a higher approximation it is often necessary to take into consideration the effect of molecular vibrations on both moments of inertia. For nondegenerate vibrations it is usually sufficient to add terms that represent simple rotation–vibration coupling. For degenerate vibrations, however, the effect of Coriolis forces is much more important. As in the case of spherical rotators, they can produce a coupling of two vibrations of different species that increases with the rotational energy and a splitting of the degenerate vibrational levels. This effect is more important if the frequencies of the two vibrations are not widely separated. For practical purposes, the selection rules outlined in the following paragraph are not modified by these interactions.

For symmetrical rotators the selection rules for rotational transitions that accompany a vibrational one depend on the direction of the transition moment with respect to the top axis. Thus, as in the case of linear rotators, parallel and perpendicular bands have different characteristic structures. For parallel bands, the selection rules are given by Equation (92):

$$\Delta K = 0, \quad \Delta J = 0, \pm 1 \tag{92}$$

with the condition that $\Delta J = 0$ transitions do not take place when $K = 0$. The corresponding selection rules that determine the structure of perpendicular bands are (Equation 93)

$$\Delta K = \pm 1, \quad \Delta J = 0, \pm 1 \tag{93}$$

The possible transitions are summarized in Figure 15(a) and (b).

If the interaction of rotation and vibration is weak, as is often the case, the above analysis indicates that the parallel bands of a symmetric rotator should exhibit the characteristic P–Q–R branch structure. However, the corresponding perpendicular bands are usually much more complicated because of the Coriolis forces. Furthermore, all nonplanar molecules in this class have the possibility of inversion. The most important case is certainly that of the ammonia molecule. It has a pyramidal structure whose equilateral triangular base

Figure 15 The energy levels (schematic) of symmetric rotators: (a) prolate; (b) oblate. Transitions indicated by solid arrows are limited to $\Delta K = 0$ (parallel bands) and those by dashed arrows by $\Delta K = \pm 1$ (perpendicular bands).

is determined by the equilibrium positions of the three hydrogen atoms. Its symmetry group is thus $_{3v}$. This structure can be inverted in the sense that the three protons can pass to equivalent positions on the other side of the nitrogen atom. The relatively low barrier to this process (approximately 5.8 kcal mol^{-1}) results in splitting of the vibrational energy levels. The separation of the two components corresponds to a frequency of 23.87 GHz, or approximately 0.79 cm^{-1}. Thus, an absorption line is

Figure 16 A portion of the ν_2 fundamental of ammonia.

readily observable at this frequency in the microwave region. The effect of this inversion process results in a doubling of the rotation–vibration spectrum, as shown in Figure 16. The two Q branches are clearly shown, each with its associated P and R branches.

5.4 Asymmetric Rotators

Very little can be said here concerning the rotation–vibration spectra of asymmetric rotators, except that they are in general very complicated. As indicated earlier, no analytical expression can be derived for the rotational energies of molecules in this class. However, computer programs are now available that provide a means of fitting observed rotational fine structure, as observed on vibrational bands in the infrared region.

6 SPECTRA OF NEAT LIQUIDS AND SOLUTIONS

The observed vibrational frequencies of molecules in neat liquids or in solution are often employed as a means of identification. However, it is well known that the frequency of a given mode of vibration of a molecule in the liquid state depends on the nature of the surrounding molecules. The vibrational frequency shifts displayed by a molecule as it passes from the free state (as in ideal gas) to its role as a molecule in a liquid environment is due to intermolecular forces. It may undergo interactions with identical molecules in a neat liquid or it may become a solute in a liquid solvent. The interaction of this molecule with its neighbors, which depends on physical quantities such as the polarity of the nearby molecules and their polarizability, have been employed in simple models of intermolecular interactions. Probably the earliest treatment of these so-called solvent effects was due to Kirkwood and to Bauer and Magat.[6] Their model, which has been modified by many authors, provides the initial basis for the interpretation of the effect of the environment on the vibrational spectra of molecules in the liquid state.

6.1 Solvent Effects

The above approach to the evaluation of the environmentally induced frequency shifts provided a semiempirical basis of the analysis of solvent effects. It was useful in the days when infrared instrumentation was relatively primitive and spectroscopists were content to measure frequencies of vibration, or perhaps the widths of absorption bands. Such quantities yielded extremely valuable analytical information concerning molecular interactions in liquids. However, with the refinement of instrumentation (in particular the development of Fourier transform techniques), as well as an important evolution of the theory of molecular dynamics in condensed phases, it has become of interest to measure and interpret the exact profile of an absorption band of a molecule in the liquid state. This approach to the analysis of the profiles of absorption bands of liquid samples will be developed briefly in section 6.3.

Some infrared spectra of acetonitrile in the liquid state are presented in Figure 17. The spectrum of the neat liquid exhibits a strong absorption band at 2253 cm^{-1}, which is assigned to the C≡N stretching vibration. The weaker feature at 2293 cm^{-1} is probably the first overtone of a mode approximately described as a C−C bond stretching.

Figure 17 Infrared spectra of acetonitrile. (Reproduced by permission of Wiley-VCH from G. Turrell, 'Bandshapes in the Vibrational Spectroscopy of Liquids I. Infrared Absorption', *Spectrosc. Eur.*, **9**(4), 8–15 (1997).)

Spectra of the same molecule in several commonly used solvents are also shown in Figure 17. It is apparent that the position of the minimum transmission of the C≡N stretching fundamental is a function of the molecular environment. On the other hand, the C−C overtone is relatively insensitive to the intermolecular forces. A careful inspection of these spectra reveals certain changes in the profiles of the observed bands. Both the widths of the C≡N stretching bands and their transmission in the wings vary with the solvent used. Furthermore, slight band asymmetries can be detected when the abscissae are developed. In particular, the broadening of the C≡N stretching band of acetonitrile provides evidence of hydrogen-bond formation with the methanol solvent. This particular interaction will be discussed in section 6.4.

6.2 Absorption Bandshapes

The shape of the wings of an absorption band of a small molecule in solution is primarily due to its hindered rotational (or orientation) motion. The effect becomes more clearly evident in the case of a diatomic solute molecule. Some early spectra of HCl in various solutions are shown in Figure 18, where they are compared with a schematic representation of the spectrum of the gas. The spectra of the dissolved molecule are characterized by the appearance of a central absorption peak analogous to the (forbidden) Q branch in the spectrum of the gas at ν_0 and its shift to lower frequencies with increasing solvent perturbation. Furthermore, the wings of the bands become less prominent as the central feature increases in intensity. It should be noted that CCl_4, a commonly used solvent in organic analytical spectroscopy, is not as ''inert'' as is often supposed. Thus, the vibrational frequencies of a molecule (especially those involving H atoms) in this solvent do not correspond to those of the isolated molecule. Furthermore, the frequency shifts become greater in polar solvents, as exemplified by the spectrum of HCl in CH_2Cl_2.

6.3 Band Broadening

When a hypothetical isolated molecule interacts with electromagnetic radiation, the processes of absorption, induced emission and/or light scattering may result. The spectra obtained are characterized by the bands due to transitions between the various quantum states of the molecules. The fact that a given transition produces a broadened feature is fundamentally due to the uncertainty principle and the Doppler effect. These origins of spectral broadening are only important in the study of gaseous samples under extreme conditions (e.g. very low pressures and temperatures – as in the stratosphere). For the routine applications considered here, where a sample

Figure 18 Infrared spectra of HCl in various solvents compared with that of the gas. (Reproduced by permission of Wiley-VCH from G. Turrell, 'Bandshapes in the Vibrational Spectroscopy of Liquids I. Infrared Absorption', *Spectrosc. Eur.*, **9**(4), 8–15 (1997).)

consists of a very large number of molecules in a liquid, the broadening and frequency shift of a given band is produced by the intermolecular interactions. Furthermore, the time dependence of these interactions results in characteristic band shapes or ''profiles''.[10]

In general, the shape of a spectral band can be described by a series of moments defined by Equation (94):

$$\mathrm{M(n)} \equiv \int_{-\infty}^{+\infty} (w - w_0)^n \hat{} (w)\, \mathrm{d}w \qquad (94)$$

where $n = 0, 1, 2 \ldots$ and $w \equiv 2\pi\nu$. The quantity w_0, which is known as the ''shifted band origin'', corresponds to the peak position of a symmetric band. Clearly, when $n = 0$, the moment M(0) is just the area of the band, the absolute intensity referred to in section 4.12. The first

moment ($n = 1$) is the shift of the position of the peak and the second moment is essentially a measure of the bandwidth. Higher moments provide specific information regarding solvent–solute interaction.

From a theoretical point of view, it is the Fourier transform of the spectral profile that leads to a description of the temporal behavior of a molecule in solution. The result is the autocorrelation function that at each instant specifies the orientation of the molecule. While this information is, at least at the present time, of limited analytical importance, it provides quantitative support for the molecular-dynamic description of the liquid state.

6.4 The Hydrogen Bond

This summary of the effects of intermolecular interactions in neat liquids, and thus those due to solute–solvent interaction, has been limited to the case of weak intermolecular forces. If a given molecule is surrounded by polar molecules, these forces become much stronger. Furthermore, in certain cases specific interactions may occur, leading, for example to chemical reactions. An intermediate situation may involve the formation of hydrogen bonds. Infrared spectroscopy provides the most important tool for the study of these important interactions.[11]

The vibrational spectrum of a simple hydrogen bond can be characterized by considering the degrees of freedom of the structure X–H···Y. In most cases the atoms X and Y are at least an order of magnitude heavier than the proton and the vibrational modes of this system can be described approximately by:

1. An X–H stretching mode of wavenumber $\bar{\nu}_s$, $X-\overrightarrow{H}\cdots Y$, where $3500 \geq \bar{\nu}_s \geq 1700\,cm^{-1}$.
2. An X–H···Y bending mode, $X-\underset{\uparrow}{H}\cdots Y$, of wavenumber in the region $1700 \geq \bar{\nu}_b \geq 800\,cm^{-1}$. It is doubly degenerate if the symmetry of rotation about the XHY axis is threefold or higher. If the XHY bond is bent, or if the groups X and Y lower the symmetry of the system, $\bar{\nu}_b$ will in principle be split into a doublet.
3. A stretching mode of wavenumber $\bar{\nu}_{XY}$, $\overleftarrow{X}-H\cdots\overrightarrow{Y}$, where $600 \geq \bar{\nu}_{XY} \geq 50\,cm^{-1}$.
4. A torsional mode $\bar{\nu}_t \geq 500\,cm^{-1}$, which occurs when X and Y are nonlinear polyatomic groups.

Although the appearance of (3) and (4) could be employed as a criterion for hydrogen-bond formation, it is usually more convenient and reliable to use the observed shifts of $\bar{\nu}_s$ and $\bar{\nu}_b$ that accompany it. Studies of a large number of hydrogen-bonded systems have shown that as $\bar{\nu}_s$ decreases, $\bar{\nu}_b$ shifts to higher wavenumbers, and the intensity and width of the $\bar{\nu}_s$ absorption band increases with increasing strength of the hydrogen bond.

A characteristic feature of the hydrogen bond, as observed in its infrared spectrum, is the extreme broadening of the $\bar{\nu}_s$ band. This behavior, which is unique to hydrogen-bonded systems, has been the subject of much discussion. Regardless of its origin, it is of obvious diagnostic value, as it is the most important criterion for hydrogen-bond formation.

An early infrared spectroscopic investigation of hydrogen bonding in methanol illustrates the specific information that can be obtained (Figure 19). From the results of this work it was possible to distinguish the absorption band associated with the O–H stretching vibration of the monomer in a relatively inert solvent from those resulting from dimers and higher polymers. The spectra were obtained from solutions of methanol in toluene. Spectrum A exhibits a relatively sharp band at $3607\,cm^{-1}$ which is assigned to the O–H stretching vibration of the monomer. This feature is clearly dominant in dilute solution. The broad band at $3502\,cm^{-1}$ arises from the formation of dimers as a result of hydrogen-bond formation. It can be considered to be characteristic of this type of interaction. The subtraction of the spectrum of the more dilute solution effectively eliminates the monomer band and reveals the weaker band at $3582\,cm^{-1}$. This band can thus be attributed to the stretching of a "free" OH group in the dimer. This result leads to the conclusion that the dimer has an open structure, rather than a cyclic one.

The example chosen here to illustrate the spectroscopic consequences of hydrogen-bond formation is from studies of the liquid state. It is of particular interest in demonstrating the evolution of this fundamental aspect of infrared

Figure 19 Infrared absorption spectra of methanol in toluene. (A) Concentration 0.25 M. (B) Difference spectrum obtained by subtracting that of a 0.1 M solution. The Nature of the Hydrogen Bond in Alcohol Dimers and Polymers', *Spectrochim. Acta*, **22**, 525–533 (1966).)

spectroscopy. More recent applications to crystals, glasses and, in particular, molecules of biological interest are described elsewhere in this volume.

7 SPECTRA OF SOLIDS

7.1 The Linear Diatomic Chain

The interpretation of the vibrations of crystalline solids is based on the one-dimensional model developed by Born.[6,12] This simple system was originally employed to estimate the specific heats of crystals, in particular, those of the sodium chloride structure. It has subsequently served as the basis for the interpretation of the vibrational spectra of crystals. The analysis of this model, the diatomic chain, will now be briefly summarized.

Consider a linear chain consisting of two types of atom arranged alternately, as shown in Figure 20. As indicated above, this one-dimensional model can be used to represent a simple ionic crystal. The distance d is then the dimension of the unit cell which contains two particles. The forces on atoms of type 1 and 2 are given by, respectively, Equation (95):

$$F_{2n} = -f'(\rho_{2n} - \rho_{2n-1}) + f(\rho_{2n+1} - \rho_{2n}) = m_1\ddot{\rho}_{2n} \quad (95)$$

and Equation (96):

$$F_{2n+1} = -f(\rho_{2n+1} - \rho_{2n}) + f'(\rho_{2n+2} - \rho_{2n+1}) = m_2\ddot{\rho}_{2n+1} \quad (96)$$

where ρ_n is the displacement of atom n along the direction of the chain. The force constants f and f' are assumed to be different, at least in this initial formulation of the problem.

Periodic solutions of Equations (95) and (96) can be proposed in the form of Equation (97):

$$\rho_{2n} = A_1 e^{2\pi i(\nu t - nkd)} \quad (97)$$

and Equation (98):

$$\rho_{2n+1} = A_2 e^{2\pi i\ \nu t - \left(n+\frac{1}{2}\right)kd} \quad (98)$$

Substitution of these expressions in Equations (95) and (96) leads to the pair of linear, homogeneous

Figure 20 The linear diatomic chain.

Equations (99) and (100) for the amplitudes A_1 and A_2:

$$[4\pi^2\nu^2 m_1 - (f + f')]A_1 + (fe^{\pi ikd} + f'e^{-\pi ikd})A_2 = 0 \quad (99)$$

and

$$(f'e^{\pi ikd} + fe^{-\pi ikd})A_1 + [4\pi^2\nu^2 m_2 - (f' + f)]A_2 = 0 \quad (100)$$

A nontrivial solution of these equations exists only if the determinant of the coefficients vanishes. Thus, the secular determinant becomes Equation (101):

$$\begin{vmatrix} f + f' - 4\pi^2\nu^2 m_1 & -(fe^{\pi ikd} + f'e^{-\pi ikd}) \\ -(f'e^{\pi ikd} + fe^{-\pi ikd}) & f' + f - 4\pi^2\nu^2 m_2 \end{vmatrix} = 0 \quad (101)$$

whose roots are given by Equation (102):

$$\nu^2 = \frac{f + f'}{8\pi^2}\left(\frac{1}{m_1} + \frac{1}{m_2}\right) \pm \frac{1}{4\pi^2}\sqrt{\left(\frac{f + f'}{2}\right)^2\left(\frac{1}{m_1} + \frac{1}{m_2}\right)^2 - \frac{4ff'\sin^2(\pi kd)}{m_1 m_2}} \quad (102)$$

For the special case in which all bonds are identical, $f = f'$, which implies equal spacing of the atoms, and Equation (102) reduces to Equation (103):

$$\nu^2 = \frac{f}{4\pi^2}\left(\frac{1}{m_1} + \frac{1}{m_2}\right) \pm \sqrt{\left(\frac{1}{m_1} + \frac{1}{m_2}\right)^2 - \frac{4\sin^2(\pi kd)}{m_1 m_2}} \quad (103)$$

The vibrational frequencies calculated from Equation (103) are plotted as functions of the wavenumber k in Figure 21, where it has been assumed that $m_1 < m_2$. Clearly, it is the positive roots of Equation (103) that are of physical significance. The curve that passes to the origin is called the acoustical branch, because the frequencies fall in the region of sonic or ultrasonic waves. The upper curve, referred to as the optical branch, represents frequencies in the optical (infrared) spectral region. The latter are of prime importance for the subject of this article.

The forms of the normal vibrations for each branch are given schematically in Figure 21 for the limiting values $k = 0$ and $k = 1/2d$. It should be noted that at $k = 0$ the optical branch represents a simple stretching of the bond between the two atoms for which their center of mass remains fixed. As the two atoms are assumed to be different, the oscillating dipole moment which results can interact with incident radiation, producing absorption in the infrared region. The acoustic vibration, on the other hand, does not result in a change in dipole moment at $k = 0$.

Figure 21 Dispersion curves and the forms of the normal modes for the longitudinal vibrations of the diatomic chain. The arrows represent atomic displacements. (Reproduced by permission of Academic Press from G. Turrell, *Infrared and Raman Spectra of Crystals*, Academic Press, London, 70, 1972.)

From Figure 21 it is seen that wave solutions of the type of Equations (97) and (98) do not exist for frequencies between $(1/2\pi)\sqrt{2f/m_1}$ and $(1/2\pi)\sqrt{2f/m_2}$. In this gap the wavenumber k is imaginary; hence waves having frequencies in this region are damped.

The diatomic chain illustrated in Figure 20 can also be used as a model of a simple one-dimensional molecular crystal, if, for example, f is associated with a covalent bond and f' is used to represent the much weaker intermolecular forces. If $f \gg f'$, the roots of Equation (103) are given approximately by Equation (104):

$$\nu_{\text{int}} \approx \frac{1}{2\pi} \sqrt{\frac{f}{\mu}} \tag{104}$$

and Equation (105):

$$\nu_{\text{ext}} \approx \frac{1}{\pi} \sqrt{\frac{f'}{m_1 + m_2}} \, |\sin(\pi k d)| \tag{105}$$

The first solution (Equation 104), which is independent of k, corresponds to the vibrational frequency of an isolated diatomic molecule, as in the ideal-gas phase. For all values of k the center of mass of each molecule remains fixed in its unit cell. The second solution arises from translational motion of the rigid diatomic molecules. The approximate solutions given by Equations (104) and (105) are appropriate to the limiting case, $f \gg f'$. In general, ν_{int} exhibits some dependence on k. Nevertheless, the above approximation is the basis of the separation which is often made of internal and external motion in crystals containing molecules or polyatomic ions.

From the preceding analysis it should be apparent that the vibrational frequencies of this one-dimensional system spread over two distinct regions. For the acoustic branch the frequencies lie between zero and $(1/2\pi)\sqrt{2f/m_1}$, whereas for the optical branch they are between $(1/2\pi)\sqrt{f/\mu}$ and $(1/2\pi)\sqrt{2f/m_1}$. In each case the former values correspond to the origin of the wavenumber scale, $k = 0$, and the latter are the vibrational frequencies at the limit of the first Brillouin zone. This limit is equal to $k = 1/2d$ in this, the one-dimensional case. The distribution of frequencies within the two limits specified above is usually referred to as the density of vibrational states. Not all of these frequencies can result in spectroscopic features, as the question of selection rules must be considered.

7.2 Three Dimensions: Crystalline Solids

The static structure of a perfect crystal can be described by successive translations of a unit cell in space. This repetition constitutes a symmetry operation in the sense that all such unit cells are considered to be identical. Thus, a symmetry group of these operations can be defined. The application of this principle leads to the definition of the 230 space groups of crystallography. The justification for this model supposes that the crystal is infinitely large in three-dimensional space, or at least large with respect to the dimensions of the unit cell. A mathematical artifice, the so-called cyclic boundary conditions, is sometimes introduced to achieve the equivalent result.

In the application of interest in this article, it is the primitive unit cell that is employed to generate the three-dimensional space of the crystal. This cell, which is the smallest geometrical motif that can be defined, is in some cases identical with the crystallographic unit cell, although it may otherwise have half or one-quarter its volume. This question, which has been addressed in several references, is basic in the spectroscopic applications of crystallography, as the vibrational spectroscopy of crystals involves their dynamic, rather than their static, description.[8,9] A starting point in the analysis of their dynamics is provided by the model of the diatomic chain, as outlined above.

The complexity of the three-dimensional vibrational problem increases very rapidly with the number of atoms in the unit cell. However, by analogy with the

one-dimensional model, solutions to the equations of motion can be written in the harmonic approximation as Equation (106):

$$\rho_n = \boldsymbol{A}_n \exp[2\pi i(\nu t - \boldsymbol{k}\boldsymbol{x}_\ell)] \qquad (106)$$

where ρ_n is a vector that specifies the displacement of atom n at a given instant. The amplitude and frequency of the descriptive wave in the crystal are represented by $\boldsymbol{A}_n$ and ν, respectively. The equilibrium position of each atom is located with respect to a suitable space-fixed origin by the vector $\boldsymbol{x}_\ell$, while $\boldsymbol{k}$ is the wave vector, a quantity that has the magnitude of reciprocal wavelength and is in the direction of propagation of the descriptive wave. As in the one-dimensional case, the dispersion relations determine the density of vibrational states in the crystal.

There are three dispersion curves for each particle in the primitive unit cell, as each has three degrees of freedom. Thus, for the simple example of a molecular crystal whose unit cell contains σ molecules, each of which is composed of N atoms, as many as $3N\sigma$ separate curves (branches) may exist. Of course, the actual number of branches may be reduced owing to degeneracies in the system. Three of these degrees of freedom correspond to acoustic modes; hence there are up to $3N\sigma - 3$ optical branches. The general form of the dispersion relations for such a system is sketched in Figure 22 for a given direction of the wave vector. The various branches have, in general, different shapes depending on the direction of $\boldsymbol{k}$.

As pointed out in the previous section in connection with the vibration of the diatomic chain, intramolecular forces are relatively strong in a molecular crystal. Hence the frequencies of the $3N - 6$ vibrational fundamentals of a molecule in the gas phase are not severely modified when the molecule is in a crystalline environment. If there are σ molecules per unit cell, there are $\sigma(3N - 6)$ possible ''internal'' frequencies – although degeneracies are usually present to reduce this number. As in the

Figure 22 Dispersion curves for a simple crystal. (Reproduced by permission of Academic Press, from G. Turrell, *Infrared and Raman Spectra of Crystals*, Academic Press, London, 76, 1972.)

corresponding limiting case of the diatomic chain, these internal frequencies are usually only slightly dependent on the wave vector, $\boldsymbol{k}$.

The remaining degrees of freedom are derived from the 3σ translational and 3σ rotational motions of the (nonlinear) molecules. However, three of these degrees of freedom are responsible for the acoustic modes of the crystal, leaving $6\sigma - 3$ as the maximum number of optical external modes. These latter, which are referred to by spectroscopists as the ''lattice vibrations'', usually fall in the far-infrared region of the spectrum of a crystal.

7.3 The Factor-group Analysis of Crystals

The analysis of the infrared and Raman spectra of crystals is based on the notion of the factor group. In effect, if a perfect crystal can be described by a space group, a symmetry group that characterizes the unit cell can also be defined. Although it is not, strictly, a point group, it has the same form as a point group, viz. it is isomorphic. As only symmetry axes of order 1, 2, 3, 4 or 6 are possible for a unit cell that can fill three-dimensional space, only 32 such groups exist. They identify the crystal classes. On the basis of this argument, the space group of a given crystal can be factored in the following form (Equation 107):

$$= \quad \otimes \qquad (107)$$

where is the group of translations of the unit cell.[6] The symbol $\otimes$ represents here the (semi)direct product. It can be shown that the point group that is isomorphic with the unit cell group can be used to determine the normal modes of vibration of the molecules in the unit cell and the selection rules for the vibrational fundamentals. Once the appropriate unit-cell group has been identified, the vibrational analysis is similar to that of an isolated molecule.

As an illustration of the factor-group method, consider crystalline methyl chloride. The symmetry of the molecule is described by the point group $_{3v}$ and the discussion presented in section 4.9 is appropriate. With the use of the character table (Table 6) the vibrational analysis of the molecule can be made as before. The results are summarized in the first column of Figure 23. The internal vibrations are numbered in decreasing order of frequency, starting with the most symmetrical IR (A_1 in this case) following Herzberg.[7] The three doubly degenerate frequencies of E species are numbered similarly. The representations of the six external degrees of freedom are also identified in Figure 23.

From the results of X-ray analysis, it is found that methyl chloride crystallizes in the side-centered orthorhombic system. Its space group is $^{12}_{2v} \equiv Bm2_1b$, with four molecules in the crystallographic unit cell. However, the primitive-symmetric or Wigner–Seitz cell contains only two molecules. They are located at sites

Figure 23 The correlation diagram for methyl chloride.

(special positions) of symmetry $_s$. One of the three planes of symmetry of the isolated molecule corresponds to the plane at the site. Of course, it contains the chlorine and carbon atoms, in addition to one of the three hydrogens. The other two hydrogen atoms are exchanged by the reflection operation with respect to this plane. The site group is a subgroup of the symmetry group of the molecule. Thus, the correlation shown on the left of Figure 23 is easily established.

The required unit-cell group is $_{2v}$, as found by simply suppressing the superscript in the Schönfiles notation for the space group. In this case the site group is also a subgroup of the unit-cell group. The correlation shown on the right of Figure 23 is established by inspection of the character tables (see Table 5).

The interpretation of the results obtained above by the analysis of the methyl chloride example can be summarized as follows. The three nondegenerate internal vibrations are not modified by the site symmetry in the crystal. The three degenerate modes of species E are, however, split by the symmetry of the local crystalline field. These three internal vibrations will then be expected to be observed as doublets in the infrared spectrum because of this site splitting.

As there are two molecules per primitive unit cell, coupling of the molecular modes of vibration becomes possible. In the present example, the three frequencies of species A_1 in the molecule are split by this correlation (or dynamic) coupling. According to the character table for the group $_{2v}$, both components of each doublet will be infrared-active. As for the three vibrations of species E in the molecule, each has been subjected to site splitting. Furthermore, each component will be further split due to coupling with its partner in the unit cell. However, as shown in Figure 23, the doublets produced by the splitting of the A'' species of the molecule in its site will produce one component in the infrared-inactive species A_2. The other component passes to species B_1 and is therefore active. The overall result for the E species of the molecule is to produce an infrared-active triplet for each of the frequencies ν_4, ν_5 and ν_6.

The magnitudes of the static and dynamic splittings described above are in general of the same order of magnitude, viz. a few wavenumbers. They cannot, therefore, be distinguished unless systematic investigations of oriented single crystals can be made. Such studies of infrared dichroism with the use of polarized infrared radiation are of extreme value, not only for structural investigations of single crystals, but also in the determination of the optical properties of films. Examples include the problem of molecular orientation of films deposited on solid substrates and that of stretched polymers.

7.4 Polymers

The linear-chain model developed in section 7.1 served as the basis for the dynamic description of a crystal. It can also be employed in the analysis of the vibrations of polymers.[6,13] It is often the case that the forces between successive motifs in a polymer chain are much stronger than the forces between adjacent chains. A given chain can then be developed by successive translation of the particular motif of which it is composed. The group of translational operations constitute the line group, while the particular motif represents an effective unit cell in this model.

Consider polyethylene as a polymer chain that can be analyzed by application of the line-group method. The repetitive motif is represented in Figure 24. The carbon skeleton of the extended chain is assumed to have a planar $[\sigma(yz)]$ zigzag structure along the y-direction and a plane of symmetry $[\sigma(zx)]$ perpendicular to it. There is a binary axis of symmetry $[C_2(x)]$ perpendicular to the plane of the carbon chain, passing through the center of inversion (i) shown in Figure 24, as well as another $[C_2(z)]$ that passes through each carbon atom. The other symmetry elements are a screw axis and a glide plane, analogous to those encountered in crystallography. They are denoted here by $C_2^s(y)$ and $\sigma^g(xy)$, respectively. The ensemble of operations associated with these elements, with the addition of the identity, form the factor group. It is isomorphic with the point group $_{2h}$. The 18 degrees of freedom of the six-atom repeat unit can be classified as shown in Table 8 with the use of the method outlined in section 7.3.

As the polymer chain has been assumed to be isolated, the external motions of translation in the x- and y-directions, as well as the rotation about the z-axis have

Figure 24 The C_2H_4 motif of the polyethylene chain.

Table 8 Line-group analysis of the extended polyethylene chain

$_{2h}$	E	$C_2(z)$	$C_2(y)$	$C_2(x)$	i	$\sigma(xy)$	$\sigma(zx)$	$\sigma(yz)$		$n^{(\gamma)}$ (tot)	$n^{(\gamma)}$ (vib)
A_g	1	1	1	1	1	1	1	1		3	3
B_{1g}	1	1	−1	−1	1	1	−1	−1	R_z	1	0
B_{2g}	1	−1	1	−1	1	−1	1	−1	R_y	3	2
B_{3g}	1	−1	−1	1	1	−1	−1	1	R_x	2	1
A_u	1	1	1	1	−1	−1	−1	−1		1	1
B_{1u}	1	1	−1	−1	−1	−1	1	1	T_z	3	2
B_{2u}	1	−1	1	−1	−1	1	−1	1	T_y	2	1
B_{3u}	1	−1	−1	1	−1	1	1	−1	T_x	3	2
χ_j	18	−2	0	0	0	0	6	2			

zero frequencies and can be removed, as for a gaseous molecule. These degrees of freedom are sometimes referred to as ''nongenuine'' vibrations. Translation in the z-direction is analogous to the acoustic vibrations of a crystal lattice, as described in the previous section. Thus, for in-phase motions of all repeat units this frequency is also equal to zero.

The number of vibrational modes in each IR is given in the last column of Table 8. Infrared activity is limited to the three species B_{1u}, B_{2u} and B_{3u}. The two B_{1u} modes are combinations of the symmetric stretching (ν_s) and bending (δ) coordinates illustrated in Figure 25. The B_{3u} modes are combinations of the antisymmetric stretching mode (ν_a) and the rocking coordinate (ρ), while the wagging coordinate (w) shown for species B_{2u} can be identified with the corresponding normal coordinate.

The analysis presented above for the vibrations of extended, normal polymer chains can be generalized to include, for example, helical chains. This problem has been described in a number of references.[6,12] Furthermore, the question of the interaction of polymer chains in a solid has also been treated. It should be emphasized that in the development of these models it has been assumed that the chains are of infinite length, or at least that their symmetry under translation is preserved. In the case of chains of finite length, the problem becomes much more complicated, as the appropriate boundary conditions must be imposed at each end of the chain. The reader is referred to more advanced presentations for the effects of these conditions on the vibrational spectra of polymer chains.[6,12]

Figure 25 The infrared-active representations and symmetry coordinates for the extended polyethylene chain. (Reproduced by permission of Academic Press, from G. Turrell, *Infrared and Raman Spectra of Crystals*, Academic Press, London, 237, 1972.)

7.5 Disordered Solids

A complete theoretical analysis of disordered solids has not as yet been developed. However, a qualitative description of these systems can be obtained on the basis of the preceding analysis of the vibrations of crystals. In section 7.3 the perfect crystal was taken as a model. However, if its translational symmetry is perturbed, the factor-group method can no longer be applied. Thus, the concept of a repetitive unit cell in space is no longer valid, as a given motif is not exactly reproduced by simple translations. Furthermore, the force field involved is not repetitive. Thus, there are three perturbations to spectroscopic analysis that are produced by the disorder of the system. The first of them has an immediate effect on the selection rules that govern vibrational transitions. All of the frequencies that contribute to the density of vibrational states in a given crystal become spectroscopically active. The result is a broadening of the infrared absorption bands, as can be seen from the simple example shown in Figure 26. The structural changes involved in the transitions from the pure crystal to a disordered system result in the other two effects, namely, modifications of the force field and kinetic effects that contribute to the effective $\boldsymbol{G}$ matrix. Obviously, the quantitative treatment of this problem is difficult.

8 CONCLUSION

From the contents of this article, it is apparent that the basic theory of infrared spectroscopy was developed many years ago. The more recent evolution of this subject has been primarily in the areas of computational methods and instrumentation. The impact of computer science has made possible the numerical treatment of spectroscopic data and, in particular, the application of the Fourier transform technique. The future will certainly see advances in the development of rapid time-resolved infrared spectroscopy, which should soon become an invaluable tool in the study of chemical reactions.

On the purely theoretical side, there remains the fundamental problem of disordered systems. These include glasses and other amorphous materials, in addition to the liquid state. The latter can be considered to be a system that is disordered in both space and time. Although it is the state of matter most generally employed in analytical spectroscopy, it still presents the most difficult challenge to molecular theorists.

The vibrational spectroscopies are those producing the entire (or part) vibrational spectrum of a sample, i.e. the collection of transition energies between its vibrational states. The simplest way to cause vibrational excitation is to allow the chemical species in its vibrational ground state to absorb an energy quantum from electromagnetic radiation of an appropriate energy, i.e. in the medium infrared (IR) or in the far infrared (FIR) regions. Transmission–absorption IR spectroscopy comprises the analysis of the quanta that are actually absorbed by a polyatomic chemical species and those that are not absorbed (so are transmitted). Other IR techniques relate to the analysis of the radiation that is emitted, diffused, or reflected by the sample. Another way to obtain part or all of the vibrational spectrum of a chemical species is to look at the inelastic scattering of beams other than IR radiation. Raman spectrometry is the analysis of the ultraviolet (UV), visible or near infrared (NIR) radiation that is scattered inelastically by the sample. Inelastic neutron scattering (INS) is the analysis of the energy of formerly monochromatic neutron beams after inelastic scattering by the sample. Analyses of the number and energies of the vibrational transitions of the sample, detected by each technique, yield information on the geometric (molecular and crystallographic) structure of the sample and on the strength and nature of the chemical bonds it contains.

1 INTRODUCTION

Any chemical species containing more than one atom – polyatomic molecules, molecular ions, molecular radicals, and any crystal – can be described in terms of atomic positions, bond lengths, and bond angles. However, any atom vibrates around its equilibrium position, giving rise to vibrational modes. At absolute zero temperature all polyatomic chemical species lie at the vibrational ground state. However, they can undergo vibrational excitation, thereby occupying higher-energy vibrational states. The energy differences between nearest vibrational states lie in the medium and FIR ranges, generally defined by the wavenumber limits: $4000–400\,cm^{-1}$, i.e. $0.496 > E > 0.0496\,eV$ for medium IR; and $400–10\,cm^{-1}$, i.e. $0.0496 > E > 1.24 \times 10^{-3}\,eV$ for FIR.

The simplest way to cause vibrational excitation is to allow the chemical species to absorb an energy quantum from electromagnetic radiation of an appropriate energy, so giving rise to a vibrational transition from the ground state to an excited vibrational state. Analysis of the quanta that are actually absorbed by a polyatomic chemical species, and those that are not absorbed (so are transmitted), gives information on the vibrational structure of these species and, consequently, on its chemical and geometric structure. These are the fundamentals of transmission/absorption IR spectroscopy, which has been under continuous development since the late 19th century and has became one of the most widely used techniques for chemical analysis.[1]

Over time, it has been recognized that other IR techniques (reflection, emission, and photothermal techniques) can also be applied, and that IR spectroscopy only gives partial information on the vibrational structure

of any polyatomic species. In fact, selection rules apply to IR light absorption phenomena, so that only those vibrational modes associated with changes in the molecular dipolar moment can be directly excited.

Another way to observe the vibrational spectrum of a chemical species is to look at the inelastic scattering of beams other than IR radiation. When such beams are scattered by a polyatomic species, some photons lose or gain energy as a result of interaction with the vibrational states of the molecule. The vibrational spectrum is obtained by measuring the difference between the energies of the incident beam and the small fraction that is inelastically scattered. If the incident photons are of relatively high energy – UV, visible, or NIR – we are dealing with Raman spectroscopy.[2] Raman observed that if a monochromatic high-energy radiation interacts with a chemical species, the scattered radiation is no longer monochromatic, now containing photons whose energy is produced by the sum or the difference of the original radiation energy with the energies of some vibrational transitions of the chemical species. As the selection rules for Raman-active modes do not correspond to IR-active modes in centrosymmetric chemical species, and only partly correspond (generally) for noncentrosymmetric species, Raman spectroscopy is in most cases complementary to IR spectroscopy.

The vibrational spectra of polyatomic chemical species also can be probed by the inelastic scattering of particles other than photons. The use of electrons gives rise to the techniques of electron energy loss spectroscopy (EELS) and inelastic electron tunneling spectroscopy (IETS). The incident particles can be neutrons, giving rise to INS spectroscopy, or atoms, giving rise to atom scattering spectroscopy (ASS). These techniques, developed in the 1960s by physicists, have found application in surface chemistry and physics. However, some may also be applied to bulk solids, such as geological and inorganic materials.

2 VIBRATIONAL MODES OF INORGANIC SOLIDS

2.1 Molecular Species

The total number of degrees of freedom associated with a chemical species containing N atoms is $3N$. If this chemical species is a molecule in the gaseous state, three of these degrees of freedom are associated with its translations and another three to its rotations, so that in the most general case six modes are associated with external motion (rotations and translations). The remaining $3N - 6$ degrees of freedom are associated with internal, i.e. vibrational, modes. However, if the molecule is linear, only two degrees of freedom are associated with rotation, because no rotational freedom exists around the molecular axis. Thus, in this particular case, the number of degrees of freedom associated with vibrations is $3N - 5$. A complete treatment of the principles of vibrational spectroscopy is beyond the aim of this article. The methods for determination of the number and the optical activity of the vibrational modes of molecular species have been given elsewhere.[3–8]

The $3N - 6$ (or $3N - 5$) degrees of vibrational freedom give rise to vibrational modes that differ in their symmetry with respect to the symmetry elements of the molecular point group and in their multiplicity. The nondegenerate modes are denoted as A or B in relation to their symmetry or antisymmetry with respect to the rotation about the principal symmetry axis. Doubly degenerate modes and triply degenerate modes are denoted E and F, respectively. The subscripts g and u denote modes that are symmetric or antisymmetric, respectively, with respect to the center of symmetry (if any); the superscript symbols $'$ and $''$ distinguish modes that are symmetric or antisymmetric, respectively, with respect to symmetry planes not containing the principal axis ($\sigma \neq \sigma_v$). The subscripts 1, 2, 3 are related to the symmetry with respect to other symmetry axes.

Character tables, which can be found in several vibrational spectroscopy books, allow the determination, for any molecular point group, of the species (or irreducible representations) in relation to the symmetry elements typical of that group. As discussed below, the classification in terms of a particular symmetry species determines the activity – IR activity, Raman activity, both IR and Raman activity, or inactivity – of any mode.

2.2 Crystalline Solids

When a crystalline solid is considered, the N atoms present in the smallest (primitive) Bravais cell must be taken into consideration to count the fundamental vibrational modes. They give rise to $3N$ total degrees of freedom, three of which give rise to translational modes of the cell as a whole, which are the acoustic modes. Thus, the vibrational degrees of freedom (optical modes) are, in this case, $3N - 3$.

If the solid is molecular, the molecules (supposed to be formed by M atoms, where $M = N/r$ with r being the number of molecules in the smallest Bravais cell) can be treated as for the gas phase, thus giving rise to $3M - 6$ (or $3M - 5$ if linear) vibrations for each molecule. The degrees of freedom associated with the external modes of every molecular unit (which are $6r$ for nonlinear molecules and $5r$ for linear molecules) give rise to lattice vibrations (frustrated translations and rotations) and to three acoustic modes. However, the internal vibrations

of each molecules should in principle give rise to *r*-fold splitting, as a result of the coupling of the vibrations within its primitive unit cell as a whole.

The analysis of the symmetry of the chemical species under study (i.e. the point group for a free molecule, or the space and factor groups for a crystal[3]), according to the site symmetry of every atom, allows the determination of the irreducible representation of the total modes. After subtraction of the translational and rotational modes (the acoustic modes for the crystals), the irreducible representation of the vibrational (or optical) modes can be obtained. This means that the number of vibrational modes belonging to the symmetry species associated with the molecular or crystal symmetry can be counted. Consequently, the number of active modes can be counted, according to the symmetry selection rules of the different techniques (in particular IR and Raman).

In principle, every vibrational mode is due to motions of the chemical species (the molecule or the primitive unit cell) as a whole. Thus, molecular and crystal dynamics calculations should rigorously define the motion of every atom of the chemical species in terms of vibrational modes. For large and complex chemical species, this approach gives rise to a very complex picture so that the results are sometimes not easily interpreted and comparison between the vibrational behavior of similar species is frequently difficult.

However, a group approximation can be frequently used, in which the vibrational modes can be attributed approximately to the movements of small groups of atoms. This is especially the case if very different bonds are present in the molecule, so that the coupling of their movements is negligible. In this way, it is possible to dissect the chemical species under study and consider separately the vibrations of groups of a few atoms (such as the functional groups in organic compounds). This makes possible a satisfactory, although approximate, interpretation of the vibrational spectra of polyatomic molecules and of some crystals, and allows easy comparison between the vibrational features of related chemical species.

In the case of crystalline solids, more than one equivalent structural unit may be present in the primitive cell. This results in splittings of the fundamental vibrational modes of these units. In the case of many crystalline solid materials covalent units (e.g. oxo anions for oxo salts) are present, together with other groups bonded by ionic bonds (e.g. the cations in the oxo salts). According to the group approximation, the internal vibrations of the covalent units can be considered separately from their external vibrations (hindered rotations and translations of the group that finally contribute to the lattice vibrations and to the acoustic modes of the unit cell) and those of the other units. If a number of covalent structural units are present in the primitive cell, their internal modes become split.

In the spectra of solids, the polar phonons (those that are IR active) split into two components, the transverse optical (TO) mode and the longitudinal optical (LO) mode. This is because the electric field associated with the transverse wave is zero, whereas that associated with the longitudinal wave is nonzero; when coupling of these modes occurs with the electric fields associated with the vibration, this gives rise to the separation $\nu_{LO} > \nu_{TO}$. This factor is relevant to the shape and interpretation of the IR spectra of solid materials, as discussed below.

2.3 Amorphous Solids

Amorphous solids differ from crystalline solids because no long-range order occurs. So, variable coupling exists between the vibrational modes of similar or equivalent structural units. Consequently, amorphous solids can be treated like liquids and gases. The vibrational spectra of amorphous materials can present a smaller number of broader features than those of corresponding crystalline materials, whereas crystal coupling effects can produce multiple sharp features. An example of this is treated below in some detail, concerning the forms of silica.

3 INFRARED SPECTROSCOPY OF INORGANIC SOLIDS

As already mentioned, a variety of IR techniques are in use to give information on the structure of different solids. When electromagnetic radiation is incident on a sample, the light may (essentially) be absorbed, reflected, or transmitted. Equation (1) follows from the conservation of energy:

$$I_0 = I_R + I_T + I_A \tag{1}$$

where I_0, I_R, I_T, and I_A are the intensities of the incident, reflected, transmitted, and absorbed radiation, respectively. Dividing Equation (1) by I_0 gives Equation (2):

$$R + T + A = 1 \tag{2}$$

where $R = I_R/I_0$, $T = I_T/I_0$, and $A = I_A/I_0$ are the apparent reflectance, transmittance, and absorptance, respectively. In any IR technique, two selection rules are valid. They are simplified as follows:

$$\Delta v = \pm 1 \tag{3}$$

$$\left(\frac{\partial \mu}{\partial Q}\right)_0 \neq 0 \tag{4}$$

Equation (3), where v is the vibrational quantum number, means that only transitions between nearest

vibrational states can directly occur in the case of the harmonic oscillator. However, this condition is relaxed in the case of anharmonic oscillators, so that not only fundamentals but also overtones and combination modes can sometimes be observed, although they are usually weak. Equation (4) indicates that only vibrational modes associated with a change in the dipole moment μ of the molecule between the extremes of the atomic displacements (Q is the normal coordinate) different from zero can be directly excited. According to the Lambert–Beer law (Equation 5):

$$A = -\log_{10}\frac{I_T}{I_0} = \varepsilon c l \tag{5}$$

the absorbance A linearly depends on the molar concentration c of the absorbing species, through the molar absorption coefficient ε and the sample path length l. This relationship (which is rigorously valid only in non-scattering media) is the basis for quantitative analysis performed through IR spectroscopies. Recent work has shown how to extend the range of Beer's law in FTIR (Fourier transform infrared) spectrometry.[9]

However, the absorbance at a particular wavelength also depends upon the population of the corresponding vibrational states. According to Boltzman's law, Equation (6),

$$\frac{N_i}{N_0} = \frac{g_i}{g_0}e^{-\Delta E/kT} \tag{6}$$

where N_i are the state populations and g_i are the state multiplicities, ΔE is the energy difference between the states 0 and i and k is the Boltzmann constant. The ΔE values for fundamental vibrational transitions fall in the IR region, so that the population of the first excited states is very small at room temperature and lower than the population of the ground state even at 1000 K. This means that only transitions originating from the ground state can be ordinarily excited at room or relatively low temperature.

Commercial FTIR spectrometers, available at moderate costs, offer short recording times (one to a few minutes at most), high resolution (0.5–4 cm^{-1}) and are capable of obtaining desirable signal-to-noise ratios for most types of sample. These performances fulfill the requirements for the study of inorganic materials, in relation to the intrinsic line width of their modes (generally some tens of wavenumbers) and the optical properties of the samples. The different experimental set-ups are described below.

3.1 Transmission–Absorption Technique

This technique was originally applied by the pioneers of IR and is probably still the most widely used, even though its application to solids involves problems of sample form and preparation. Working with monocrystals or large particles is difficult, due to the high amount of absorbing species necessarily placed in the IR beam. However, this technique can be successfully applied to powdered materials, even though a problem arises from the radiation scattering.

When a radiation is incident on a nonabsorbing layer consisting of N particles per unit volume, its intensity decreases exponentially with the sample thickness x, following Equation (7):

$$I_T = I_0 e^{-\varphi x} = I_0 e^{-N\sigma x} \tag{7}$$

Thus an apparent absorbance A' can be defined (Equation 8) for an absorbing and scattering medium:

$$\begin{aligned} A' &= -\log_{10}\frac{I_T}{I_0} = 0.43N\sigma x = 0.43N(\varepsilon' + s)x \\ &= A + 0.43Nsx = A + S' \end{aligned} \tag{8}$$

where φ is the linear attenuation coefficient and σ is the linear attenuation coefficient of one particle. The coefficient σ contains a component due to absorption, ε', and a component due to scattering, s. So the apparent absorbance is composed of the true absorbance A superimposed upon the component due to the light scattering S'. This simplified approach is similar to that given by Henry[10] who proposed Equation (9) for the component dependent on scattering:

$$S' = kx\,d\frac{(n-1)^2}{\lambda^2} \tag{9}$$

where k is a constant independent of λ but dependent on the particle arrangement, d is the particle diameter and n is the refraction index of the material. However, according to the Rayleigh theory, S' depends on the third power of the particle diameter (and so linearly on the particle volume) and on the fourth power of the radiation frequency ν. Studies of effect of scattering on the IR transmission spectra of powder samples[11,12] have shown that if the particle diameter is sufficiently small (considerably smaller than the IR wavelength), the scattering of the IR radiation is very small. Thus, finally, the apparent absorbance of a layer of a powder depends on its own absorptivity, on the disk thickness and density, on the particle size, and on the wavelength.

To obtain a good quality powder sample for the transmission–absorption IR technique, it is necessary to prepare a layer appropriately diluted and sufficiently thin. The most used technique uses KBr pressed disks. KBr is an easily available powdered material which is not absorbing in the medium IR region (down to near

Table 1 Materials used for discs and windows that transmit medium IR or FIR radiation

Name	Formula	Frequency range (cm^{-1})	Comments
Sodium chloride	NaCl	$\nu > 590$	Hygroscopic, water soluble
Potassium bromide	KBr	$\nu > 340$	Hygroscopic, water soluble
Cesium iodide	CsI	$\nu > 200$	Very hygroscopic
Calcium fluoride	CaF_2	$\nu > 1140$	Not hygroscopic, allows high temperature
Barium fluoride	BaF_2	$\nu > 840$	Not hygroscopic, allows high temperature
Silver chloride	AgCl	$\nu > 450$	Soft, not hygroscopic
Silver bromide	AgBr	$\nu > 300$	Soft, not hygroscopic
Polyethylene	PE	$625 > \nu > 33$	Low temperature, no organic solvents
Quartz	SiO_2	$\nu > 2500$	Only high ν
Sapphire	α-Al_2O_3	$\nu > 1780$	Only high ν
Zinc sulfide	ZnS	$\nu > 840$	Not hygroscopic
Germanium	Ge	$\nu > 600$	Hard, brittle, high reflection loss
Zinc selenide	ZnSe	$\nu > 455$	Low absorption
Cadmium telluride	CdTe	$\nu > 320$	Quite soft
Thallium bromide, iodide	Tl(Br,I)	$\nu > 250$	Toxic
Silicon	Si	$\nu > 660-400 > \nu$	Hard, brittle, high reflection loss

400 cm^{-1}, i.e. it cuts out the FIR). It can be easily mixed homogeneously with the powder to be investigated, and pressed, thus obtaining diluted self-supporting disks very useful for IR transmission. The spectra so obtained give rise to a baseline due to scattering that gives very high transmission in the low-frequency region (down to the cut-off near 400 cm^{-1} due to absorption by KBr itself). Other materials (see Table 1) give similar pressed disks, with cut-off limits at even lower frequencies, but are more expensive. Alternatively, the powders can be simply deposited in the form of a thin layer on a disk of a transmitting medium.

As KBr and the other alkali halides absorb in the FIR region, other binding materials must be used. The preparation of disks with polyethylene (which is transparent in most of the FIR region) is the most used technique. However, in this range the scattering is very low because of the long wavelengths involved, so that it is sometimes possible to simply deposit the powder on a disk of a transmitting material (see Table 1) using a solvent that later evaporates.

Another technique, used mostly in the past, is to mull the powder with organic liquids, such as liquid paraffin (nujol) and perhalogenated organics. The powder is mixed to make a paste from which a layer is formed. Absorptions from the mulling liquid (i.e. in the C–H stretching and deformation regions for paraffin oils, or C–X modes for halocarbons) also occur and obscure some spectral regions.

3.2 Reflection Techniques

When incident radiation interacts with a flat surface, the reflectances of the parallel and perpendicular polarized light with respect to the incidence plane, $R_\parallel$ and $R_\perp$, are given by Equations (10) and (11):

$$R_\parallel = \frac{\varepsilon\cos\theta - \sqrt{\varepsilon - \sin^2\theta}}{\varepsilon\cos\theta + \sqrt{\varepsilon - \sin^2\theta}}^2 \tag{10}$$

$$R_\perp = \frac{\cos\theta - \sqrt{\varepsilon - \sin^2\theta}}{\cos\theta + \sqrt{\varepsilon + \sin^2\theta}}^2 \tag{11}$$

where ε is the complex dielectric constant of the material (assumed to be isotropic) and θ is the incidence angle. From these relationships it follows that the reflected light is mainly polarized perpendicular ($R_\perp$ is large, whereas $R_\parallel$ has a minimum for $0 < \theta < 90$). When $\theta = 0$, substituting $\varepsilon = (n - ik)^2$ gives Equation (12):

$$R = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2} \tag{12}$$

where n and k are the real and imaginary parts of the absolute index of refraction. For conducting materials, such as metals, the refraction index is totally imaginary, which means that $n = 0$ so that $R = 1$ at any frequency, and the radiation is totally reflected. This is the case of total (or specular) reflection.

For insulating or weakly semiconducting materials, such as most inorganic compounds, $k = 0$ and n is nearly constant (i.e. the index of refraction is real) in the IR spectrum except near the absorption frequencies, i.e. for $\nu > \nu_{LO}$ and $\nu < \nu_{TO}$. This means that outside of the latter skeletal region, monocrystal surfaces of inorganic compounds only weakly reflect the radiation, R being smaller with greater n. This means that all light is essentially transmitted or, better, refracted. However, for $\nu_{LO} > \nu > \nu_{TO}$, the index of refraction is imaginary and $k > 0$ goes through a maximum. This means that near the skeletal absorption region, R again becomes

Figure 1 (a) FTIR reflectance spectrum of an MgO monocrystal (incidence angle 26.5°, face [001]). (b) FTIR and FT/FIR absorption–transmission spectra of MgO powder. (Reproduced with permission from G. Busca, *Catal. Today*, **27**, 323–352 (1996).)

near to 1, i.e. the skeletal vibrations of inorganic compounds give rise not only to absorbed radiation in transmission experiments but also to reflected radiation in the reflection experiments (the reststrahlen effect). Thus, the specular reflectance for insulating materials, both in the form of monocrystals[5] and in the form of sintered pellets,[13] is frequently the basis for the best determination of the skeletal spectrum, as far as the IR-active modes are concerned.

Figure 1 shows the reflection spectrum of an MgO monocrystal compared with the transmission–absorption spectrum of MgO powder. MgO (periclase) has the rock-salt structure (space group $Fm3m \equiv O_h^5$, with $Z = 4$, and with one formula unit only in the smallest Bravais cell). The six degrees of freedom associated with the two atoms in the primitive cell give rise to a triply degenerate acoustic mode and to a triply degenerate optical mode. The irreducible representation for the optical modes is given by Equation (13):

$$\Gamma_{\text{opt}} = F_{1u}(\text{IR}) \tag{13}$$

Thus, rock-salt-type compounds are Raman-silent (as far as the fundamentals are concerned, see below) and only show one IR-active fundamental mode. The TO quoted for MgO at $401\,\text{cm}^{-1}$ (Figure 1, curve a) corresponds to the lower frequency limit of the reflectance band, whereas the LO corresponds to the higher-energy limit of the reflectance, and is quoted at $718\,\text{cm}^{-1}$. For $\nu_{\text{LO}} > \nu > \nu_{\text{TO}}$ the reflectance is strong and almost constant, but outside these limits the reflectance is very small. The transmission–absorption IR spectrum of the MgO powder shows the maximum slightly above ν_{TO} ($407\,\text{cm}^{-1}$ in the spectrum of a polyethylene disk) and a shoulder near ν_{LO}. Other components arise from particles with different morphologies[14] although it has been shown that the microcrystal powder spectrum of MgO is also affected by surface relaxation.[15]

The total reflection of IR incident light at any wavelength from a surface can occur in two cases: (a) when the beam arises from a transmitting medium and is incident on the surface of a conducting material; and (b) when the beam arises and is incident within a transmitting medium, but the medium from which the beam arises has a higher refraction index than the other, and the incidence angle is greater than the limit for refraction.

It has been recognized in the first case that if molecules are adsorbed on the surface of a metal, only part of the grazing incident radiation is reflected, with part being absorbed by the adsorbed species. This absorption is greatly increased if the incident radiation is polarized perpendicular to the metal surface. This is infrared reflection absorption spectroscopy (IRRAS) which, mainly after the work of Greenler[16] and Pritchard,[17] is applied widely to surface studies on metal surfaces. Under these conditions, the additional selection rule of Equation (14)

applies:

$$\left(\frac{\partial \mu_{\perp}}{\partial Q}\right)_0 \neq 0 \tag{14}$$

which means that only the adsorbate vibrations associated with a change in the dipole moment perpendicular to the crystal surface are detectable. The total reflection technique can be applied to detect the growth of oxidic layers over metal surfaces (i.e. the skeletal bands of the oxide layers) and this is a widely applied technique in corrosion and electrochemical research,[18,19] colloid chemistry,[20] coating technology,[21] and heterogeneous catalysis.[16,17]

The second case is internal reflection spectroscopy, utilized in attenuated total reflection (ATR)[22] where an absorbing layer is deposited on one or two external surfaces of a prism. The light penetrates the prism from a free surface and is multiply reflected by the other faces. During the reflection, part of the light penetrates the external layer and is absorbed by it. Thus, in the case of the internal reflection techniques the reflectance is given by Equation (15):

$$R = 1 - A = 1 - \varepsilon c d \tag{15}$$

where d is the thickness of the layer penetrated by the radiation, c is the molar concentration of the absorbing species in that layer, and ε is the molar absorption coefficient of that species. This technique has found application in the examination of several bulk solids (e.g. polymers[23,24]), electronic devices (e.g. those constituted by silica layers on silicon[25,26]), and glasses.[27] This technique can also be applied to metal layers at the interface with a solution and in this case the signal can be surface enhanced.[28] This technique is of wide interest in the fields of electrochemistry[29] and colloid chemistry.[30] An interesting variation is cylindrical internal reflection (CIR).[31–33] As an example of use, a hydrogel slurry can be analyzed using cylindrical crystals immersed in the medium so that IR radiation is multiply transmitted and reflected at the internal surface. This technique could be successfully applied to heterogeneous catalytic systems at the water/solid interface, or in stages of catalyst preparation (e.g. zeolite syntheses).

Another interesting variant of the total reflection technique is surface electromagnetic wave spectroscopy (SEWS), which consists in the generation of a surface plasmon on a substrate by frustrated total internal reflection in a prism located a few micrometers from the surface. This plasmon is decoupled by a second prism. Some interesting results have been reported with this technique concerning surface species on alumina.[34]

3.3 Diffuse Reflectance

The IR spectroscopy of powders in the diffuse reflectance mode has grown strongly, aided by the commercialization of appropriate attachments and cells. This technique is particularly attractive because it does not require much sample preparation (the powder is simply deposited in a sample holder). As this technique takes advantage of light scattering, it is very useful for studies in surface chemistry.

This technique requires collection of the radiation scattered by the sample with appropriate collecting mirrors, such as an integrating sphere. Most photons are essentially simply scattered, but those corresponding to the energies of vibrational transitions are potentially absorbed. The interpretation of diffuse reflectance spectra is based on the phenomenological theory of Kubelka and Munk.[35–37] The Kubelka–Munk (K–M) function is given by Equation (16):

$$f(R_\infty) = \frac{(1 - R_\infty)^2}{2R_\infty} = \frac{k}{s} \tag{16}$$

where R_∞ is the reflectance of an infinitely thick layer and may in practice be substituted by $R_\infty - R'_\infty$ (i.e. by the reflectance spectrum from which the reflectance of a transparent reference material such as KBr has been subtracted). The K–M function depends linearly on the absorption coefficient k (such that $k = 2303\varepsilon c$, where ε is the molar absorption coefficient and c is the molar concentration) and inversely on the scattering factor s. Obviously, the greater the absorption coefficient and the smaller the scattering, the higher the K–M function. An approximation of the K–M function is that k is treated as a variable but s is assumed constant. This is not true in the vicinity of strong absorptions.

More realistic and complex theories have subsequently been developed,[38–41] according to the quite complex nature of the phenomena involved in the diffuse reflectance of light. Experimental studies[42–45] showed that this technique is affected by particle size, granulometric distribution, and the index of refraction of the particles; the latter has an important role when the particle size is near the wavelength of the IR radiation. Diffuse reflectance infrared Fourier transform (DRIFT) studies in the FIR region allow the detection of the skeletal spectra of materials, such as mixed oxide catalysts, pigments, metal halides.[46]

One important practical problem in diffuse reflectance measurement is the need to cancel the specular reflectance by the front surface of the sample, which generates negative bands in the DRIFT spectrum, so causing apparent shifts in the true absorption bands. This is achieved by using appropriate cell designs in commercial DRIFT attachments (see Figure 2).[47,48]

Figure 2 Diagram of a DRIFT accessory designed to avoid the collection of totally reflected light. (Reproduced with permission from A.N. Davies, *Spectrosc. Eur.*, **6**(4), 25–28 (1994).)

3.4 Emission Technique

According to Kirchhoff's law (Equation 17),

$$\varepsilon = \frac{I_{em}}{I_b} = \alpha \tag{17}$$

the emittance ε (i.e. the ratio of the light emitted by the sample I_{em} with respect to that emitted by a blackbody at the same temperature, I_b) is equal to the absorptance, α, of the sample. The emissivity is proportional to the fourth power of the temperature difference between the emitting sample and the detector (Stefan's law). This implies that emissivity is sufficiently strong at relatively high temperatures to give a good signal-to-noise ratio in a large part of the IR spectrum. In fact, the blackbody emission below 1000 K shows its maximum in the medium IR region. According to Koenig[23,24] the emission spectra of polymers can be taken at above 70 °C with sufficiently good signal-to-noise ratios in the range 1800–450 cm^{-1} (outside this range the signal-to-noise ratio is very low). As pointed out by Griffiths et al.,[49] temperatures well above 500 °C are needed to have a sufficiently good signal-to-noise ratio in the CH stretching region near 3000 cm^{-1}.

A number of problems arise in connection with the use of infrared emission spectroscopy (IRES). One of them arises from the existence of temperature gradients that can cause self-absorption of the emitted radiation by the colder outer parts of the sample itself; another is concerned with selective reflection that occurs in the vicinity of strong absorption bands. This reduces the absorptance and hence the emittance. Moreover, perturbations can be created by reflections and emission by the cell elements. However, these problems can in part be overcome so that IRES can be successfully used in the fields of polymers[23,24] and corrosion science.[50] The IRES of metal oxides in the field of surface chemistry and catalysis has been reviewed recently by Sullivan et al.[51] These authors reported several examples of emission spectra of oxide catalysts and of adsorbates on supported metals, and cite at least 11 papers concerning metal oxide surfaces. Some of the advantages of this technique are the very easy sample preparation and its easy applicability at high temperatures (150–400 °C). It can be applied to investigate the temperature dependence of the radiative properties of materials, such as glasses.[52] Figure 3 is a diagram of an IRES attachment.

3.5 Photoacoustic and Photothermal Techniques

When an IR beam is incident on a solid surface it can be absorbed in part, and this leads to its conversion into heat. If the beam is modulated (as in any interferometers such as those of FTIR instruments) and the solid is in contact with a gas (air, He, Ar, ...), its conversion

Figure 3 Experimental arrangements for IRES. (Reproduced with permission from D.H. Sullivan, W. Curtis Conner, M.P. Harold, *Appl. Spectrosc.*, **46**, 811–818 (1992).)

to heat gives rise to an acoustic signal. In fact, the periodic temperature rise so obtained causes a periodic modulation of a gas pressure in the cell that can be detected by a sensitive microphone (Figure 4). This acoustic signal will be the more intense the stronger is the absorption at a particular wavelength. Reflected and scattered light are not absorbed and hence do not cause a photoacoustic signal. However, light absorbed by the gas over the sample causes signals. This makes necessary the use of monoatomic nonabsorbing gases (He, Ar, . . .). The photoacoustic effect, discovered as early as in 1880 by Bell,[53] could be successfully applied essentially only after the work of Rosencwaig and Gersho[54,55] in 1976. The main limitations of this technique are: (a) it requires a gaseous atmosphere; (b) the cell needs a microphone close to the sample (see Figure 7) so the sample cannot be heated and otherwise activated conveniently; and (c) the technique has an intrinsically low signal-to-noise ratio. However, the photothermal effect is much more efficient for species in the vapor phase than for bulk and surface species. Photoacoustic spectrometry (PAS) is not exactly a surface spectroscopy, because the penetration of the thermal effect is always significant. The extent of this depends on the modulation frequency, which varies with wavenumber in a Fourier transform (FT) spectrum. The PAS technique has found successful applications in polymer science,[23,24] surface carbon studies and coal characterization,[56,57] and in heterogeneous catalysis.[49,58–62]

Another technique is photothermal beam deflection spectroscopy (PBDS), based on the mirage effect first reported by Boccarra et al.,[63] and developed in the IR region by Low et al.[64] In this case, the periodic temperature rise caused by the absorption of the modulated IR radiation (i.e. the photothermal effect) is detected optically because it causes periodic deflections of a laser beam passing close to the surface of the

Figure 4 Diagram of a photoacoustic cell.

Figure 5 Diagram of FTIR PBDS set-up. (Reproduced with permission from C. Morterra, M.J.D. Low, *Langmuir*, **1**, 320–326 (1985).)

solid sample (Figure 5). The PBDS technique has some advantages over PAS because of its lower limits of sample dimensions, but has disadvantages because of the critical geometric set-up. As for PAS, PBDS can have advantages with respect to traditional IR for the detection of surface vibrations in very opaque materials. This has resulted in the application of PBDS to carbons and coals.[56,57]

4 RAMAN SPECTROSCOPY OF INORGANIC SOLIDS

The Raman effect is based on the inelastic scattering of electromagnetic radiation by molecular vibrations. When the radiation is incident on a sample, some photons are scattered due to the dipole moments induced through the static polarizability of the electrons. This is Rayleigh or elastic scattering. However, a small number of photons are scattered through modulation of the polarizability by electronic, vibrational, or rotational motion, leading to Raman or inelastic scattering.

Using a simple classical model it is easy to demonstrate[65] that when a chemical species is irradiated at the frequency ν_0 and its polarizability is modulated at the vibrational frequency ν_1, the time dependence of the induced dipole moment μ is given by Equation (18),

$$\mu(t) = \alpha_0 E_0 \cos 2\pi\nu_0 t + \frac{1}{2}\left(\frac{\partial\alpha}{\partial Q}\right)_0 Q_0 E_0 \cos 2\pi(\nu_0 + \nu_1)t + \frac{1}{2}\left(\frac{\partial\alpha}{\partial Q}\right)_0 Q_0 E_0 \cos 2\pi(\nu_0 - \nu_1)t \quad (18)$$

where α is the polarizability, which is a function of the normal coordinate Q in a Taylor's series

Figure 6 FTIR transmission–absorption spectrum (KBr and polyethylene disks, broken line) and FT/Raman spectrum (full line) of a commercial TiO_2 anatase powder. (Reproduced with permission from G. Busca, *Catal. Today*, **27**, 323–352 (1996).)

(Equation 19):

$$\alpha = \alpha_0 + \left(\frac{\partial \alpha}{\partial Q}\right)_0 Q + \frac{1}{2}\left(\frac{\partial^2 \alpha}{\partial Q^2}\right)_0 Q^2 + \cdots \qquad (19)$$

where α_0 is the static polarizability and E_0 is the amplitude of the radiation. The three terms in Equation (18) correspond to Rayleigh scattering (with $\nu = \nu_0$), to anti-Stokes–Raman scattering (with $\nu = \nu_0 + \nu_1$) and to Stokes–Raman scattering (with $\nu = \nu_0 - \nu_1$), respectively. From a quantum-mechanical treatment it is possible to rationalize why anti-Stokes–Raman scattering is far weaker than Stokes–Raman scattering, in particular for high frequency modes.

It is possible to conclude that Raman scattering occurs only if Equations (20) and (21) hold:

$$\Delta v = \pm 1 \qquad (20)$$

$$\left(\frac{\partial \alpha}{\partial Q}\right)_0 \neq 0 \qquad (21)$$

This also means that in Raman spectroscopy only transitions between nearest levels and those associated with changes in the polarizability α upon motion are allowed for a harmonic oscillator. The first selection rule is relaxed for anharmonic oscillators. Group theory shows that for centrosymmetric chemical species Raman-active modes are IR inactive, and vice versa. This is the mutual-exclusion rule. Other modes can be both IR and Raman inactive. For noncentrosymmetric molecular species, modes also occur that are both IR and Raman active.

The Raman scattering process is inherently weak (only a small fraction of photons are scattered, about 10^{-6}) and this limit is expected to be even more important for surface species. The intensity of the Raman signal of adsorbed species can be enhanced by surface-enhanced Raman scattering (SERS) that is, however, limited to rough surfaces of a few highly reflective metals.[66,67]

Raman spectroscopy of inorganic materials offers advantages over IR spectroscopy because of the weak Raman scattering intensity from the skeletal vibrations of ionic oxides and (generally) the absence of TO/LO splitting, offering rather high resolution, and high spatial resolution allowing microspectroscopy. As an example, the FTIR and FT/Raman skeletal spectra of a TiO_2 anatase powder sample are compared in Figure 6.

One of the problems with Raman spectroscopy is the superimposition of the Raman effect by fluorescence phenomena. To avoid this, FT/Raman spectrometers working with NIR lasers have been developed. Alternatively, anti-Stokes–Raman spectrometry may be used in spite of the weakness of the anti-Stokes–Raman signal.[68]

5 INELASTIC NEUTRON SCATTERING SPECTROSCOPY

Among the techniques based on the inelastic scattering of particles, the INS techniques allow important data to be obtained for the vibrational characterization of solids. The INS technique[69,70] consists of the analysis of the energy distribution among neutrons inelastically scattered by the chemical species under study, generally presented in a dispersed form such as in the form of powders. If the instruments operate with a polychromatic continuous

Figure 7 Diagram of a time-of-flight INS spectrometer. (Reproduced with permission from H. Jobic, in *Catalyst Characterization, Physical Techniques for Solid Materials*, eds. B. Imelik, J.C. Vedrine, Plenum Press, New York, 347–375, 1994.)

neutron source (from a fission nuclear reactor), the dispersion of the scattered beam is obtained before the sample by Bragg reflection from a single crystal operating as a diffraction monochromator.

However, if the instrument works with a pulsed neutron beam (spallation source) the energy analysis is obtained by using the time-of-flight technique, i.e. by measuring the time of arrival at the detector of the scattered neutrons after the pulse, through the source–sample–detector route. This arrangement is shown in Figure 7.

The INS technique has many disadvantages with respect to the much easier IR technique, essentially associated with the limited availability of a neutron beam source, the complexity of the neutron energy dispersion, and the neutron detection complexities. Moreover, the resolution is much smaller (near 2% of the energy transfer, which means 20 cm^{-1} at 1000 cm^{-1}); to increase the signal-to-noise ratio the spectra are usually recorded at very low temperatures.

In principle, there is a great advantage of INS with respect to both IR and Raman spectroscopies, because there are no selection rules and so all vibrational transitions are in principle INS active. However, the intensity of the INS peaks depends on the INS cross-section of all the atoms involved in the corresponding vibrational mode. This cross-section is characteristic of each element and does not depend on its chemical environment; it is at least 40 times greater for hydrogen than for any other element. Thus, the peaks associated with modes that involve hydrogen motions dominate the spectra, whereas those that do not involve hydrogen motions can be so weak as to be undetectable.

It is evident that INS spectra are particularly useful for the detection of vibrational transitions involving hydrogen-containing species and hydroxy groups. This is particularly true for the vibrational transitions associated with adsorbed hydrocarbons, hydroxyls and water on zeolites[71,72] and of hydrogen and absorbed species adsorbed on metallic catalysts (the latter, when unsupported, cannot be studied by IR and Raman), as well as hydride species on oxide and sulfide catalysts.[73–76] In the latter cases, these absorptions can fall into the region below 1000 cm^{-1}, where metal–oxygen and metal–sulfur skeletal vibrations occur and dominate IR and Raman spectra. As the skeletal vibrations of oxides and sulfides are very weak in INS spectra, those involving hydrogen are detected easily. This technique has been applied successfully to the analysis of hydrogen bonds in solids, such as the analysis of hydrogen bonds in metal hydroxides including iron oxyhydroxides,[77] the free proton dynamics in γ-MnO_2,[78] and hydrogen bonding in ices.[79] Low-energy vibrational modes in oxides have also been studied.[80]

6 APPLICATIONS OF VIBRATIONAL SPECTROSCOPIES TO THE CHARACTERIZATION OF INORGANIC SOLIDS

Several collections of IR, Raman, or both IR and Raman spectra of inorganic materials and minerals have been published[81–84] and are available electronically.[85] The following discussion briefly reviews some of the

applications of vibrational spectroscopies in the fields of characterization of such materials. A database of standard Raman spectra of minerals and related inorganic crystals has been published.[86]

6.1 Simple Anhydrous Oxides

Within basic inorganic chemistry[87–89] the oxides of nonmetals are defined as acidic oxides or anhydrides, whereas the oxides of metals are denoted as basic oxides. Some oxides have both acidic and basic character and are consequently defined as amphoteric. The bulk properties of these compounds are related to their crystal chemical features and are also reflected in their bulk vibrational properties.

6.1.1 Ionic/Covalent Nature of Solid Oxides and Their Vibrational Features

The oxides of low-valency metals (i.e. with cations of oxidation number $\leq +4$) are typically ionic compounds. They are most frequently easily obtained in crystalline forms.

For sufficiently small cations ($r < 0.8$ Å) the oxide structures are determined by cubic or hexagonal close packing of oxide ions with the cations in tetrahedral or octahedral interstices.[90–93] Bigger cations do not enter such interstices, so that structures with less densely packed oxide ions (e.g. simple cubic) and higher coordinations for the cations must occur (seven or eight). In ionic metal oxides coordination of the cations (four to eight) is generally higher than the valency (one to four) and this also occurs for the coordination of O^{2-} oxide ions (three to six).

The oxides of nonmetals are characterized by the considerable covalent nature of the bond between the nonmetal and oxygen, in agreement with the high electronegativity of the nonmetal elements. This frequently results in molecular structures for the nonmetal oxides, some of which are gaseous or liquid in normal conditions. Some form cyclic polymeric molecules and are solid in normal conditions (e.g. Se_4O_{12}, P_4O_{10}). By decreasing the element electronegativity, covalent network structures are formed for semimetal oxides (e.g. B_2O_3 or SiO_2 in their room-pressure forms). Although they can form crystalline phases, the solid oxides of semimetals are also characterized by the existence of very stable amorphous states and by their glass-forming properties.[94] These metastable amorphous or vitreous structures find many applications (e.g. for silica) and can be converted into stable crystalline phases at very high temperatures.

The covalent nature of the solid nonmetal oxides (molecular or network) is shown by the coordination around the element that either corresponds to its valency or is even lower. In such structures, the oxygen is either bridging between two metal atoms or bonded to one atom only with a former double bond.

The bulk acidity of these nonmetal solid oxides is associated with the acidity of the product of their reaction with water, giving an oxo acid. The acidity of oxo acids is associated with the strong covalency of the nonmetal–oxygen bond, which subtracts electronic charge from the oxygen atom thus allowing the O–H bond to be highly polarized and stabilizing the negative charge of the anion produced by dissociation. However, the acid strength of oxo acids is primarily enhanced by the presence of doubly bonded oxygen atoms around the nonmetal atom, which allows delocalization of the negative charge produced by the acid dissociation. For this reason, the higher the oxidation state of the nonmetal, the more the oxygen atoms are doubly bonded, and the stronger is the acidity of the oxo acid.

The oxides of the metal elements in very high oxidation states (e.g. Mn^{VII}, Cr^{VI}, Mo^{VI}, W^{VI}, V^{V}, Nb^{V}, Ta^{V}) are also frequently denoted as anhydrides, and give rise, by reaction with water, to acid species (sometimes polyoxoacids) that can be strongly acidic. Due to the high oxidation states of the metal elements in these compounds, their electronegativity is very high,[95] so the oxides and the derived acids have nearly the same properties as those from nonmetal oxides and acids.

The structural properties of the compounds of metals in very high oxidation states ($\geq +5$) differ from those of nonmetals, in that the coordination around the metal atom is elastic and can be very distorted. For example, the overall coordination of pentavalent vanadium[96] and hexavalent molybdenum in their oxides is frequently quite arbitrarily defined, and can vary from four to six depending on the environment. Sixfold coordination for these ions is frequently very distorted, with one or two very short metal–oxygen bonds and one or two very long so that, excluding the longest bonds, sixfold coordination frequently approaches fourfold coordination.[97]

In network oxide structures the metal–oxygen bonds are all almost equivalent, so that their movements couple extensively. Also, the stretching and deformation vibrations mix. As a result, assignments of the different vibration modes can be very approximate. However, the higher-frequency vibrational features are generally associated with stretching modes. The position of these modes can be assumed to be primarily dependent on the coordination of the involved metal ions and on the extent of the condensation of the resulting polyhedra (Table 2). This approach has been proposed by Tarte[98,99] and is a useful approximation for the interpretation of the IR and Raman skeletal spectra of oxides of unknown structure. However, and perhaps more correctly, analysis of the spectra suggests that the higher-frequency modes are

Table 2 Absorption range (cm^{-1}) of some elements and coordinated compounds

Atom X	Tetrahedral XO_4 (isolated)	Octahedral XO_6	
		Pure oxide	Isolated complex
Ge^{IV}	700–800	700–800	~500
Ti^{IV}	650–800	–	500–400
Al^{III}	700–850	–	500–350

Zn^{II}	400–650	<300	–
Fe^{II}	–	<350	–

mainly to be assigned to motions of the lighter oxygen atoms, so that they can be assigned to stretchings of oxygen in different coordination states. This alternative approach, first proposed by Beattie and Gilson,[100] is shown in Table 3.

Most simple oxide structures have been the object of extensive studies and complete vibrational analysis. Some examples are summarized in Table 4.

6.1.2 Silica

The different polymorphs of silica – α- and β-quartz, α- and β-cristobalite, tridymites, coesite, morganite, and silicalite – all have tetrahedrally coordinated silicon. Their vibrational structures, as well as that of amorphous or vitreous silica,[101,102] where Si is also tetrahedral, can therefore be discussed in parallel.

The IR spectra of all tetrahedral silica polymorphs have bands in three regions: 1300–950 cm^{-1}, very strong, hereinafter denoted ν_1; 850–600 cm^{-1}, medium strength, ν_2; and near 450 cm^{-1}, very strong, ν_3. Raman spectra show very weak peaks in the 1300–950 cm^{-1} and 850–700 cm^{-1} regions, and one or more very strong peaks below 550 cm^{-1}, in a position very sensitive to the overall crystal structure of the solid (ν_4). These features, also present in the spectra of amorphous or vitreous silica, represent vibrations of the basic structural units of both crystalline and amorphous silica, namely SiO_4 tetrahedra and bridging oxygens. Additional sharp peaks can be found in the IR and Raman spectra of crystalline polymorphs in the region below 700 cm^{-1}, which are associated with splittings of the above modes, due to crystal structure effects, and to torsional lattice modes.

The interpretation of the spectra of silica polymorphs can be attempted on the basis of a model assuming the bridging Si_2O, or T–O–T monomeric unit, as done by Bell and Dean[103] and by Galeener[104] for amorphous silica. This approach gives rise to a picture agreeing with that arising from the lattice dynamics calculations of van Santen et al.[105,106]

An oxygen atom in any tetrahedral-based SiO_2 polymorph or zeolite is bonded symmetrically with two tetrahedral cations (T) giving rise to a bent T–O–T group. Assuming that this group is symmetrical and isolated, the site symmetry of oxygen is C_{2v}. So, the three degrees of freedom of any oxygen atom consist of two in-plane movements (A_1 and B_1) and one out-of-plane movement (B_2). The B_2 movement is associated with the out-of-plane deformation of the T–O–T group, the B_1 with the asymmetric stretching, whereas the A_1 mode has the character of both a symmetric stretching and an in-plane bending mode (scissoring). According to this, the three main IR bands observed in all silica polymorphs are classically assigned to the asymmetric stretching (arising from the A_1 mode, ν_1), to the in-plane bending (arising

Table 3 Typical oxygen-atom vibrational modes for metal oxide structures

[a] R = Raman; in = inactive.

from the B_1 mode, ν_2) and to the out-of-plane rocking (arising from the B_2 mode, ν_3) of the T−O−T groups. However, in this manner the movements of Si (or T) atoms are neglected, and the interpretation of the Raman spectra is difficult. However, if account is taken of an isolated symmetric Si_2O molecule (C_{2v} point group) where Si atoms also are free to move, its total of nine degrees of freedom (six of which arise from silicon and three from oxygen) constitute three translations, three rotations, and three vibrations. The three vibrations are the asymmetric stretching (B_1), the symmetric stretching (A_1) and the bending mode (A_1), whereas the B_2 mode becomes a rotation. So, if Si atoms are free to move, the in-plane motion of oxygen (A_1 symmetry) splits into two components, a bending mode (ν_2) and a symmetric stretching mode (ν_4). By analogy, and by developing the central force network model of Sen and Thorpe,[107] Galeener[104] showed that four main vibrational modes are expected for a tetrahedral silica network, i.e. a symmetric stretching, an antisymmetric stretching, a bending, and a rocking mode. In the C_{2v} symmetry of the T−O−T bent units, the modes with A_1, B_1, and B_2 symmetry are both IR and Raman active. The strongest Raman mode, ν_4, is assumed by Galeener[104] to be a symmetric stretching mode mainly because the Raman peak intensity is generally greater for stretching than for bending modes. However, the coupling of this mode with the scissoring mode provides an explanation of the low frequency of the strongest Raman peak (550–350 cm^{-1}) in all silica polymorphs. It is also clear that in the solid state, in order for all T−O bonds to expand in phase, most T−O−T angles must contract simultaneously. This mode is consequently highly sensitive to the structure of the polymorph, as is indeed observed. The position of the strongest Raman peak, ν_4, in fact, strongly depends on the type of rings present in silicas and silicates, as shown by Sharma et al.,[108] and on the density of the unit cell, as shown by Kingma and Hemley for silicas.[102] This is shown in Table 5.

As for the IR spectrum, the strongest complex band is ν_1, observed in the 1300–950 cm^{-1} region, and is associated with the asymmetric stretching of the T−O−T bridges. However, as recently pointed out by Kamitsos et al.,[109] this mode is split into two components even in the case of vitreous silica, due to either the in-phase ($\nu_{1'}$) or the out-of-phase coupling ($\nu_{1''}$) of the asymmetric stretching modes of the nearest T−O−T groups. In other words, this mode couples with the symmetric and asymmetric stretching of the four Si−O bonds of the SiO_4 octahedra. As shown in Table 5, it seems clear that the position of both $\nu_{1'}$ and $\nu_{1''}$ components is also somewhat

sensitive to the size of the rings and/or to the density of the different silica polymorphs. This is particularly true for $\nu_{1''}$, whose shift is stronger, so that it is only sometimes resolved from $\nu_{1'}$.

The ν_1 modes are detectable in nearly the same position as in the Raman spectra, but are very weak there because of the small change in polarizability of T–O–T bonds during the asymmetric stretching if the two T atoms are equal.

As discussed above, the ν_2 mode is essentially a bending mode of the T–O–T bridges, although mixed with a symmetric stretching mode, as assumed by Flanigen et al.[110] Its assignment predominantly to a bending mode is mainly due to its weakness in the Raman spectra, although its position is more typical of a symmetric stretching mode. This mode appears to be the least sensitive to the structure, although in some cases it splits definitely into more components, as in the case of α-quartz where three well-resolved sharp bands are found.

The lowest-frequency IR mode ν_3 is associated with the out-of-plane deformation of the T–O–T bridges, i.e. a rocking mode. This explains why this mode is essentially silent in the Raman spectrum, while being very strong in the IR region 430–490 cm^{-1} in all silica forms, as well as in zeolites.

In addition to the four vibrational modes discussed here that are common to all silicas, network silicates, and aluminosilicates, other structure-sensitive features are

Figure 8 FTIR and FT/FIR transmission spectra of amorphous silica (aerosil), α-quartz and kaolinite powders (KBr and polyethylene disks).

frequently present. They are associated with the splitting of these vibrational modes (bands above 350 cm^{-1}) or to torsional lattice modes (below 400 cm^{-1}).

Figure 8 compares the FTIR and FT/FIR transmission–absorption spectra of an amorphous silica sample (aerosil) and of a crystalline powder (α-quartz). The ν_1, ν_2, and ν_3 absorptions (broad) are evident for amorphous silica. In the case of quartz, more, sharper components are observable, as expected: 10 maxima can be easily observed at 1165, 1086, 798, 779, 694, 519, 463, 397, 373, and 263 cm^{-1}. The irreducible representation for α-quartz (taking the right-handed enantiomorph with space group $P3_221 = D_3^6$, with $Z = 3$) is $4A_1(R) + 4A_2(IR) + 8E$ (R,IR) so that 12 IR-active fundamental modes are expected, each one undergoing TO/LO splitting. In the ν_1 region (asymmetric Si–O–Si stretching) three fundamental modes are expected, so that in the maximum at 1086 cm^{-1}, which shows shoulders on both sides, more components are superimposed. Three resolved components are found as expected in the ν_2 region. One fundamental mode is expected to be very weak near 130 cm^{-1},[111] but could not be detected.

The difference between the network silicate structure of the silica and the layer silicate structure of kaolinite is mainly shown by the presence, in the case of kaolinite, of a strong band with maxima at 940 and 913 cm^{-1}, typically due to Si–(OH) terminal stretchings. In this region silicas and network silicates do not absorb.

Another form of silica, called silicalite, belongs to the MFI IUPAC zeolite code, which belongs to the $P2_1/n = C_{2h}^5$ monoclinic space group (number 14) with $Z = 96$ (1,18). It transforms into an orthorhombic structure, belonging to the $Pnma = D_{2h}^{16}$ space group (number 62) between 350 and 363K. Substituted silicalites like ZSM5 zeolite (see below) and Ti-silicalite take the orthorhombic structure even at room temperature, the transition temperature being strongly shifted to lower temperatures.

The factor group analysis for monoclinic silicalite[112] gives the following irreducible representation for the optical modes:

$$\Gamma_{opt} = 216\ A_g\ (R) + 216\ B_g\ (R) + 215\ A_u\ (IR) + 214\ B_u\ (IR)$$

For the orthorhombic structure the following irreducible representation is obtained:

$$\Gamma_{opt} = 110\ A_g\ (R) + 106\ B_{1g}\ (R) + 110\ B_{2g}\ (R) + 106\ B_{3g}\ (R) + 106\ A_u\ (\text{inactive}) + 109\ B_{1u}\ (IR) + 105\ B_{2u}\ (IR) + 109\ B_{3u}\ (IR)$$

Accordingly, 429 IR-active modes and 432 Raman-active modes are expected for the monoclinic structure and 323 IR-active modes and 432-Raman active modes are expected for the orthorhombic form. The maxima really observable for silicalite are reported, together with those of other silica polymorphs, in Table 5. We observed only 16 components in the IR spectrum and 11 components in the Raman spectrum, because of the superimposition of many of the expected fundamentals. However, careful observation of the spectra, with the help of analysis of the perturbations arising from isomorphic substitution and with the aid of derivative spectra, showed the presence of a great number of very weak components (shoulders) in the spectra.

6.2 Complex Oxides

There are many ways to combine oxide components, producing a so-called mixed oxide. They depend not only on the preparation procedure adopted, but also on the nature of the component oxides. We will summarize them here below.

6.2.1 Mixing of Ionic Oxides

Several pairs of ionic oxides with the same crystal structure present extended or total reciprocal solubility. In other cases only limited solubility occurs, mainly due to their too-different cationic size. Limited reciprocal solubilities are also found for oxides having different structures but the same stoichiometry. Very limited solubilities are frequently found for ionic oxides having different stoichiometries, and these form mainly metastable phases. In any case, the resulting solid solutions retain the ionic character of the metal–oxygen bond. The characteristics of the vibrational behavior of such solid solutions are similar to those of the component oxides, although small band shifts are generally found between the positions typical for the spectra of the two component oxides.

Alternatively, oxides with different stoichiometry can mix, giving rise to ternary phases that are characterized by structures very different from those of the pure compounds. If the two cations are both sufficiently small, mixed oxide phases with oxide close packing structures (either hcp or ccp) are formed, with cations in tetrahedral or octahedral interstices. Spinels (formed by a bivalent and a trivalent metal in a 2 : 1 atomic ratio) and ilmenites (a bivalent and a tetravalent element in a 1 : 1 atomic ratio) are examples. Alternatively, one of the two cations can enter into oxide close packing, but the other can be too large, needing higher coordination numbers than six. This generates other structures such as the β-aluminas (a monovalent or a bivalent element with a trivalent element in ratios 1 : 17–1 : 19) and perovskites (two trivalent elements or one bivalent and one tetravalent in 1 : 1 atomic ratios).

From the point of view of vibrational spectroscopies, the treatment of such complex oxides does not differ significantly from those of the pure ionic oxides. Data on ternary oxide phases with the ABO_3 stoichiometry are given in Table 6.

6.2.2 Mixing of Covalent Oxides

Covalent oxides can also give rise to more or less extended solid solutions (such as those of MoO_3 and WO_3) and compounds, which can be treated similarly to the pure covalent oxide structures; sometimes they are treated as the salts (see below).

Table 6 Crystal structures of some solid ternary-oxide structures with the stoichiometry ABO_3, and the irreducible representations of the optical modes

Structure type	International symbols	Schönflies notations	Z	Irreducible representations[a]
Ilmenite	$R\bar{3}$	C_{3i}^2	6	$5A_g\,(R) + 5E_g(R) + 4A_u(IR) + 4E_u(IR)$
$LiNbO_3$	$R3c$	C_{3v}^6	6	$4A_1(IR) + 5A_2(R) + 9E\,(IR,R)$
Cubic perovskite	$Pm3m$	O_h^1	1	$3F_{1u}(IR) + F_{2u}(in)$
Tetragonal perovskite	$P4mm$	C_{4v}^1	1	$3A_1(IR,R) + 4E(IR,R) + B_1(R)$
Orthorhombic perovskite	$Pnma$	D_{2h}^{16}	4	$7A_g(R) + 7B_{1g}(R) + 5B_{2g}(R) + 5B_{3g}(R) + 8A_u(in) + 7B_{1u}(IR) + 9B_{2u}(IR) + 9B_{3u}(IR)$
Rhombohedral perovskite	$R\bar{3}c$	D_{3d}^6	2	$A_{1g}(R) + 3A_{2g}(in) + 4E_g(R) + 2A_{1u}(in) + 2A_{2u}(IR) + 4E_u(IR)$
Calcite	$R\bar{3}c$	D_{3d}^6	2	$A_{1g}(R) + 3A_{2g}(in) + 4E_g(R) + 2A_{1u}(in) + 2A_{2u}(IR) + 4E_u(IR)$
Aragonite	$Pmcn$	D_{2h}^{16}	4	$9A_g(R) + 6B_{1g}(R) + 6B_{2g}(R) + 9B_{3g}(R) + 6A_u(in) + 8B_{1u}(IR) + 8B_{2u}(IR) + 5B_{3u}(IR)$

[a] R = Raman; in = in active.

6.2.3 Mixing of Covalent and Ionic Oxides: the Oxo Salts

Ionic and covalent oxides mostly give rise to ternary phases, known as oxo salts. Examples are metal silicates, phosphates, molybdates, tungstates, chromates, and vanadates. Their structures have little in common with those of the pure oxides. Frequently, different salts can be produced starting from the same oxide components, in relation to the different compositions, as for *ortho-*, *pyro-*, and *meta*-vanadates, silicates, and phosphates.

The oxo salts contain covalent structures (the oxo anions) ionically bonded to cations. This allows easy distinction of some vibrational modes involving the nonmetal atom (or the higher oxidation state metal) from those involving the metal atom.

6.3 Vibrational Features of Complex Oxides of Practical Interest

6.3.1 Cuprate Superconductors

Vibrational spectroscopies have largely been used to characterize these superconductor ceramics.[113] However, most studies involve Raman spectroscopy and IR reflection measurements of monocrystals. Additionally, the interpretation of such measurements is mostly performed using lattice dynamics calculations. This approach, although very complete in principle, does not always give rise to a good fit between calculated and theoretical frequencies and does not allow easy comparison between the vibrational features of different structures. The interpretation of IR spectra of superconducting powders based on the group approximation has also been attempted.[114,115] From these studies, some conclusions can be drawn allowing the comparison of the spectra of different superconducting cuprates:

- The highest frequency IR and Raman modes are due to stretchings of the basal Cu–O bonds.
- The position of the higher-frequency Cu–O asymmetric stretching mode easily correlates to the length of the basal Cu–O bonds.
- Loss of resolution for the individual components is typical for samples approaching the composition that allows superconductivity to occur at low temperature.[114,116]
- Modes parallel to the Cu–O square planes are screened out when the structures become able to undergo the superconducting transition due to doping effects, such as for YBCO,[117] $Nd_{2-x}Ce_xCuO_4$,[114,118] $La_{2-x}Ba_xCuO_4$, and $La_{2-x}Sr_xCuO_4$.[115]

6.3.2 Ferrite Magnetic Materials

Many ferrimagnetic materials, used as magnetic pigments or as permanent magnets, belong to two classes of ferrites. The soft ferrites are based on inverted spinel structures (Fe_3O_4, $MnFe_2O_4$, mixed $(Mn,Zn)Fe_2O_4$, $MgFe_2O_4$, $CoFe_2O_4$). The cubic spinel structure, irrespective of the cation distribution of normal, inverted or random spinels, belongs to the $O_h^7 = Fd3m$ space group with $Z = 8$. Five Raman-active modes and four IR-active modes occur; both IR[119–121] and Raman spectroscopies[122,123] have been used to characterize such structures. Also the magnetic ferric oxide maghemite (γ-Fe_2O_3) can be assumed to belong to the same family although its distorted defective spinel-like structure is far more complex, and possibly still not defined with certainty. The IR[124] and Raman[123] spectra of γ-Fe_2O_3 are also definitely more complex than that of spinels, showing that the maghemite structure is actually a superstructure. The other class of ferrite materials is the hard ferrites. The best known example is barium ferrite, $BaFe_{12}O_{19}$, which takes the magnetoplumbite structure (space group $P63/mmc = D_{6h}^4$, with $Z = 2$) of $PbFe_{12}O_{19}$. IR studies have been devoted to barium ferrite magnetic materials, giving further information on the structure and the likely dynamic disorder involving one ferric atom between two sites, one located in a mirror plane and the other out of it.[124,125]

6.3.3 β-Alumina-type Ionic Conductors

One of the most relevant families of ionic conductor solids are the so-called β-aluminas. The parent compound is sodium β-alumina whose composition (when stoichiometric) is $NaAl_{11}O_{17}$. Spectroscopic investigations have been devoted to this compound[126,127] as well as to other compounds of the same family.[124]

These phases are characterized by the existence of layered blocks of a trivalent element (most frequently Al^{3+}, but also Fe^{3+} and Ge^{3+}) with the same spinel structure separated by mirror planes. The big monovalent (Na or K), bivalent (Ba and sometimes Ca or Sr) and trivalent (La) cations, which do not enter the cubic close packed array of oxide ions of the spinel blocks, are located together with oxide anions bridging between the blocks. In these planes the cations are able to diffuse. The metal–oxygen stretchings involving such ions located in the mirror planes fall in the low-frequency (FIR) region. For this reason FIR and Raman spectroscopy have been devoted to studies of the coordination and mobility of such cations.[124,128,129]

6.4 Metal Hydroxides

The solid crystalline hydroxides are generally formed from condensed polyhedra containing the metal element surrounded by oxygen atoms. The hydrogen atoms are located externally to the polymeric structures and are involved in hydrogen bonding. Thus the skeletal spectra of hydroxides show features typically arising from the OH

groups, and features to be assigned to the vibrations of MO_x polyhedra. For the latter features, the considerations already made for oxides are valid.

The vibrations of hydroxy groups are typically composed of O–H stretchings (3800–2000 cm^{-1}, depending on the extent of hydrogen bonding), in-plane bending (1200–800 cm^{-1}), and out-of-plane deformation (generally below 1000 cm^{-1}). The multiplicity of such modes depends upon the number of hydroxy groups present in the smallest Bravais cell and in the coupling of their vibrations, and is also dependent on the hydrogen-bonding patterns.

The vibrational spectra of alkali metal hydroxides have been reviewed by Ryskin and Farmer.[130] The centrosymmetric structures of LiOH and NaOH, both containing two formula units per unit cell, give rise to two OH stretching modes, one of which is IR active and the other Raman active. In the case of KOH, whose structure is not centrosymmetric and again contains two formula units per unit cell, a split both of IR- and Raman-active peaks is detectable. The positions of these peaks (in the 3680–3600 cm^{-1} region) show that no hydrogen bonding occurs in these structures.

The structure of brucite $Mg(OH)_2$ is assumed by most bivalent hydroxides. Every layer of $Mg(OH)_2$ contains MgO_6 octahedra with three triply-bridging hydroxy groups pointing up and three pointing down, alternately. The unit cell of the brucite structure contains only one $Mg(OH)_2$ unit, so 12 optical modes should exist. Two OH stretching modes exist, one Raman active (symmetric stretching, A_{1g}, 3655 cm^{-1}) and one IR active (asymmetric OH stretching, A_{2u}, 3700 cm^{-1}). The positions of these modes show that no hydrogen bonds occur in this structure. Additional two doubly-degenerate deformation modes occur, again one Raman active (E_g) and one IR active (E_u). Finally, two IR-active modes ($A_{2u} + E_u$) and two Raman-active modes ($A_{1g} + E_g$) are associated with vibrations of the MgO_6 octahedra. Lutz et al. compared the vibrational structures (IR, Raman, and INS) of several brucite-type hydroxides,[131] as well as oxyhalides of bivalent metals in the fundamental[132] and overtone regions.[133]

The goethite or diaspore structures of α-AlOOH, α-FeOOH, α-CrOOH and α-GaOOH have orthorhombic unit cells, belonging to $Pbnm = D_{2h}^{16} = 62$ space group with $Z = 4$. The overall unit cell and the smallest Bravais cell coincide and contain 16 atoms; thus 45 vibrational modes are expected. All atoms occupy the 4*c* Wyckoff position in the cell on a reflection plane (C_s site symmetry). According to literature data,[134,135] and separating the modes due to the hydrogen-bonded OH groups from those of the Me–O skeleton, the irreducible representation for the IR optical modes of α-MeOOH is as follows:

$$\Gamma_{Me-O} = 5B_{1u}\,(IR) + 2B_{2u}\,(IR) + 5B_{3u}\,(IR)$$

$$\Gamma_{O-H} = 2B_{1u}\,(IR) + 1B_{2u}\,(IR) + 2B_{3u}\,(IR)$$

Consequently, the IR spectrum is expected to contain 17 fundamental modes. Clearly, not all will be resolved. A typical feature of the spectra of these compounds is the presence of two IR-active OH stretchings, giving rise to a strong band with a shoulder at the higher frequency in the IR spectra (3126 and 3050 cm^{-1} for goethite, 3000 and 2920 cm^{-1} for diaspore, and 2913 and 2840 cm^{-1} for α-GaOOH) as well as two strong bending modes (891 and 796 cm^{-1} for goethite, 1080 and 970 cm^{-1} for diaspore, and 1019 and 952 cm^{-1} for α-GaOOH), which have been discussed in terms of the geometry of the hydrogen-bonding situations. The materials α-(Cr,Fe)OOH[136] and α-(Fe,Ga)OOH,[137] forming goethite-type solid solutions, have also been characterized by IR. The INS spectra of goethite have also been reported.[77]

X-ray diffraction (XRD) analysis indicates that boehmite γ-AlOOH and lepidocrocite γ-FeOOH crystallize in the space group $Cmcm = D_{2h}^{17}$, i.e. space group 63 with $Z = 4$. However, XRD analysis does not reveal the position of the hydrogen atoms. To obtain information on the position of the hydrogen atoms, vibrational spectroscopies can be used. The IR spectra are dominated by two well-split OH stretchings at 3295 and 3090 cm^{-1} for boehmite and at 3390 and 3125 cm^{-1} for lepidocrocite. Some authors have concluded that the IR spectra of boehmite, in particular the modes associated with the vibrations of the hydroxy groups, are consistent with the space group *Cmcm*,[134,138] whereas others have concluded that a lower symmetry space group applies, namely $Cmc2_1 = C_{2v}^{12}$ of space group 36.[139] Publication of the Raman spectrum by Kiss et al.[140] confirmed that the mutual exclusion rule applies, so the noncentrosymmetric space group $Cmc2_1$ must be ruled out, the true space group for boehmite being *Cmcm*.

More recently, boehmite spectra have been compared with those of samples containing small amounts of silica.[141] Three different behaviors for the IR bands of boehmite upon Si addition can be noticed: (a) some bands are essentially not perturbed or are only slightly shifted by silicon addition; (b) other bands progressively decrease in intensity; and (c) others are eliminated even with a very small amount of silica addition. In particular, the bands lost through silicon addition are those at 325, 398, 412, 1161, 3088 and 3305 cm^{-1}, i.e. bands associated with the vibrations of the Al–OH groups. The bands near 1070 and 735 cm^{-1} decrease progressively in intensity by Si addition. However, the three bands at 608, 483 and

Table 7 Assignment of the observed IR and Raman peaks of boehmite and changes caused by Si addition

IR bands (cm^{-1})	Assignments	Behavior on Si addition
3302	ν O–H	Removed
3088	ν O–H	Removed
2097	Combination	
1972	Combination	
1161	δ O–H	Removed
1072	δ O–H	$\rightarrow$1066, slowly decreasing in intensity
sh 870	Combination	Superimposed by ν Si–O
sh 775	Combination	Superimposed by ν Si–O
735	γ O–H	Slowly decreasing in intensity
608	ν Al–O	$\rightarrow$619
483	ν Al–O	$\rightarrow$470, $\rightarrow$478
412	ν Al–OH	Removed
398	ν Al–OH	Removed
368	ν Al–O	$\rightarrow$357
325	ν Al–OH	Removed

sh = shoulder; $\rightarrow$ = shift to.

368 cm^{-1} shift only slightly, but retain their strengths and shapes.

This behavior has allowed slight modification of the assignments of the low-frequency Al–O stretching bands, as shown in Table 7, with respect to those reported in the literature. Thus, as described above, six IR-active modes are expected for the Al–O stretchings of boehmite. Three of them, which are not perturbed by Si addition, can be assigned to Al–O stretchings (the bands at 608, 483, and 368 cm^{-1} in pure boehmite). The other three, which are eliminated by silicon addition, could be due to Al–(OH) stretching modes (at 412, 398, and 325 cm^{-1}) in pure boehmite.

The addition of Si causes new bands to occur at 3450, 880, 800, and near 405 cm^{-1}. The bands at 880, 800 and near 405 cm^{-1} are probably associated with Si–O modes. They can be associated with orthosilicate species $(SiO_4)^{4-}$, the first two bands being due to the symmetric and asymmetric stretchings and the last to a deformation mode (see below). The evident perturbation of the modes associated with the Al–OH groups suggests that most silicate species go to the interlayer region between the boehmite layers.

6.5 Hydrated Compounds

Gas-phase or isolated water molecules belong to the C_{2v} point group and give rise to three optical modes, $2A_1 + B_1$, all of which are IR and Raman active. The two stretchings are at 3756 cm^{-1} (B_1, asymmetric stretching) and at 3657 cm^{-1} (A_1, symmetric stretching), whereas the bending mode (A_1) is at 1594 cm^{-1}. When water molecules are incorporated into a crystal, their six external modes (arising from frustrated rotations and translations) contribute to lattice modes called librations of water molecules (wagging, rocking and twisting modes) and to the acoustic modes. When water is coordinated through oxygen lone pairs to cations (aquo complexes) the metal–oxygen stretching mode and the corresponding deformation modes appear and couple with the other metal–ligand vibrations. The metal–oxygen stretchings are usually located below 600 cm^{-1}. At slightly higher frequencies (900–500 cm^{-1}) the wagging and twisting modes of coordinated water molecules become internal vibrations of the aquo complex. Coordination per se causes relatively weak perturbations of the stretching and bending modes of water. However, coordination is frequently associated with additional hydrogen-bonding of water, with other water molecules, or with anions present in the crystal structure. This can result in strong downward shifts (to 2000 cm^{-1}) and broadening of the stretching absorptions, whereas the bending modes are not very sensitive and always fall in the region 1700–1550 cm^{-1}. Asymmetric hydrogen bonding (bonding to only one of the two protons of water) gives rise to spectra where sharp high-frequency peaks occur together with broad low-frequency OH stretching modes.[142]

Spectra of molecular water molecules in crystals and complexes have been collected by Ryskin[130] and by Nakamoto.[8] Protonated forms of water such as the oxonium ion H_3O^+[143] have also been investigated.

6.6 Oxo Salts

The oxo salts involve oxo anions, which are internally held by covalent bonds between the nonmetal atom (or the metal in a very high oxidation state) and oxygen, giving rise to M–O bond orders ranging between 1 and 2. The oxo anions are further bonded through ionic interactions with the metal cations. The vibrational spectra of oxo salts are therefore dominated, in their high-frequency ranges, by the internal vibrations of the oxo anion. The following sections briefly review the vibrational structure of such anions, in relation to the point group symmetry they can take. Obviously, the splittings of these internal vibrations occur in principle as a result of couplings between the modes of more than one oxo-anionic unit simultaneously present in the smallest Bravais cell.

However, when the unit cell is centrosymmetric the mutual exclusion rule is valid, so that Raman-active modes are IR inactive and vice versa. In practice, for centrosymmetric cells containing N oxo anions, every internal vibrational mode of the oxo anion gives rise to $N/2$ IR-active modes and $N/2$ Raman-active modes.

The cation–anion vibrations (lattice vibrations) are mainly located in the FIR region and their assignments,

based on similar considerations to those reported for ionic oxides, are frequently difficult.

6.6.1 *Salts with Trigonal-planar and Pyramidal MO_3^{n-} Oxo Anions*

The movements of the four atoms present in MO_3^{n-} oxo anions give rise to a total of 12 modes, six of which are associated with the movements of the anion as a whole (rotations and translations, which contribute to the lattice vibrations and to the acoustic modes of the solid). So, six ''internal'' vibrations occur. The highest symmetry point group for this ion is D_{3h}, occurring when it is planar trigonal and isolated. This is typical for isolated carbonate, nitrate and orthoborate anions. In this case, as shown in Table 8, the symmetric stretching gives rise to a nondegenerate Raman-active mode, whereas the asymmetric stretching is doubly degenerate and both IR and Raman active. Two deformation modes occur, the out-of-plane deformation (δ_{oop}) which is IR active, and in-plane deformation (δ_{ip}) which is degenerate and both IR and Raman active. By lowering the symmetry, e.g. to the C_{2v} point group (as occurs when only two of the three oxygen atoms are equivalent), the doubly-degenerate modes split and all six modes become both IR and Raman active.

The highest symmetry point group for nonplanar pyramidal MO_3^{n-} oxo anions (such as sulfite, selenite, and tellurite anions) is C_{3v}. In this case as well, all modes are both IR and Raman active. The symmetric stretching and deformations are nondegenerate whereas the asymmetric modes are doubly degenerate. Such a degeneracy is broken when symmetry is further lowered. Typical positions for the corresponding modes are reported in Table 9.

The commonest crystal structures for AMO_3 salts that have been the subject of vibrational studies are calcite ($CaCO_3$, $AlBO_3$, $FeBO_3$, $LuBO_3$, $NaNO_3$),[144] dolomite ($CaMg(CO_3)_2$), and aragonite ($CaCO_3$, $LaBO_3$[145]), including aragonite–strontianite solid solutions[146] and nitrates of bivalent metals.[147]

6.6.2 *Salts with Tetrahedral MO_4^{n-} Oxo Anions*

Most of the MO_4^{n-} oxo anions take a tetrahedral-like coordination. In this case there are nine internal vibrations plus six external vibrations contributing to lattice vibrations and to acoustic modes. When the ion takes its highest symmetry (T_d point group) the symmetric stretching and the symmetric deformation are Raman active, the last being doubly degenerate. The asymmetric stretching and deformation are both IR and Raman active and are triply degenerate. By lowering of the symmetry, the degeneracies are broken and all modes can become IR

and Raman active. This is shown in Table 10, where the typical positions of such modes are also reported for different oxo anions.

Among the different structures of salts containing tetrahedral-like oxo anions AMO_4, scheelite structures (molybdates of Ca, Sr, Ba, Pb, and Cd, tungstates of Ca, Sr, Ba, and Pb) have been the subject of many studies.[148–153] The structure of α-$MnMoO_4$ (isostructural with β-$MgMoO_4$ and β-$CoMoO_4$)[154] and the structures taken by divalent chromates[155] and sulfates[156] have also been investigated. As for compounds with the formula A_2MoO_4, studies are reported for spinel structures (Na and Ag molybdate, Na tungstate, Ni silicate, and several germanates),[157,158] olivine and monticellite structures such as Mg_2SiO_4 and some germanates,[159,160] beryllium silicate structures (Be silicate, Li molybdate and tungstate[149]), and isomorphous alkali chromates and sulfates.[161,162] Among compounds with the formula $A_3(MO_4)_2$ studies have been reported on Mg, Ca, Sr and Ba vanadates[163,164] as well as Ba and Sr orthophosphates, arsenates, chromate and manganate(VI).[165] The IR and Raman spectra of the perrhenate compound Hg_2ReO_5[166] and of Li_4SiO_4 and Li_4GeO_4[167] have been reported.

The structure of $Mg_3(VO_4)_2$ and the coordination of the vanadate ion in this structure are shown in Figure 9. This compound crystallizes in the $Cmca = D_{2h}^{18}$ space group with $Z = 4$. The crystallographic unit cell contains two Bravais cells. Figure 10 shows the IR and Raman spectra. In Table 11 the distribution and assignment of the optical modes are summarized, whereas Table 12 offers a tentative detailed assignment for the V–O stretching mode, showing the effect of decreasing of the symmetry of the anion in the crystal and of coupling of the four units.

The tetrahedral oxo anions can retain one or two protons in the crystal structure, giving rise to monohydrogen or dihydrogen ortho anions. In this case, one or two of the oxygens are certainly unequivalent to the others, and the vibrations of the O–H group also appear. Several studies have appeared concerning metal monohydrogen orthophosphates and dihydrogen orthophosphates.[168–170]

6.6.3 Salts with Condensed Tetrahedral Oxo Anions

6.6.3.1 Dimeric Condensed Tetrahedral Anions $[X_2O_7]^{n-}$
Salts where the tetrahedral oxo anions are condensed through common oxygen atoms are denoted by the prefix "pyro" (for dimeric species) or "meta" (for polymeric species). The oxo anions involved have terminal M–O bonds (six in total for dimeric pyro species, two of each atom for polymeric meta anions), and additionally contain M–O–M bridges. Such bridges are generally bent, but they can sometimes be linear, such as for some pyrosilicates, pyrogermanates, pyrophosphates, and pyroarsenates. When the bridge is bent it gives rise to an asymmetric stretching, bending/symmetric stretching modes (both are in-plane modes) and an out-of-plane rocking mode (like the Si–O–Si bridges of silica, discussed above). For silicates, the ν_{as} Si–O–Si and ν_{sym} Si–O–SiO occur in the regions 1050–900 cm^{-1} and near 650 cm^{-1}, respectively.[171,172] According to Lazarev[173] a linear relationship exists between the bond angle and the parameter $\Delta = (\nu_{as} - \nu_{sym})/(\nu_{as} + \nu_{sym})100$. When the bridge is linear (as in thortveitite, $Sc_2Si_2O_7$), the symmetric stretching could become IR inactive (or very weak if the environment is symmetric). The difference $\nu_{as} - \nu_{sym}$ is apparently a little higher, with the

symmetric stretching mode shifted somewhat down to 660–630 cm^{-1}.[174,175]

Several studies have been devoted to compounds containing condensed tetrahedral anions $[X_2O_7]^{n-}$[176] such as pyrovanadates,[165] dichromates, pyrosulfates, pyroselenates, pyrophosphates, pyroarsenates,[177] and pyroniobates.[178] Typical of these compounds are the vibrations of the bridging oxygens. Additionally, the spectra show the vibrations of the terminal MO_3. Each terminal MO_3 moiety gives rise to one symmetric and two asymmetric stretchings, one symmetric and two asymmetric bendings, as well as to one twisting and two rocking modes.

6.6.3.2 Metasilicates, Layer Silicates, and Framework Silicates The vibrational spectra of the different kinds of chain and ring silicates are dominated by the vibrations of the Si–O–Si bridges (as previously discussed for amorphous silicas and for the pyrosilicates) and of Si–O– terminal bonds.[179] Layer silicates[180,181] also present absorptions for Si–O–Si bridges and terminal silanol groups, Si–OH. Both terminal silicate bonds $Si-O^- M^+$ and silanols give rise to strong IR bands in the region 950–1000 cm^{-1}, which frequently occur also in the Raman spectra. Cyclic structures and particular conformations of the chains can give rise to characteristic features, particularly in the lower frequency regions (Si–O–Si rockings and lattice modes). Terminal silanols, such as those present in the case of layer silicates, also give rise to OH stretching modes strong in IR, such as those of kaolinite (see Figure 8), and these have been characterized by Raman spectrometry.[182] Systematic treatments of the vibrational structures of silicates have been reported.[81,82,173]

Zeolites are microporous framework aluminosilicate materials of great interest in heterogeneous catalysis and

adsorption technology. Some are natural materials, others are synthetic. The electrostatic imbalance arising from the substitution of Al for Si in the silica-like framework is balanced by protons or extraframework cations lying in the cavities. The protonic forms are used as solid acids, whereas the cation-exchanged forms are very useful for selective adsorption. Figure 11 shows the IR and Raman spectra of a typical protonic zeolite, H-ZSM5. This is the Al-containing form of orthorhombic silicalite, discussed above. For this structure there are 323 IR-active modes and 432 Raman-active modes. These spectra show the most typical features of network silica, as discussed above, with few splittings because of the superimposition of many vibrational modes arising from the same vibrations of the basic Si–O–Si units. Figure 12 shows the IR spectrum of the zeolite NaX, a typical cation-containing zeolite whose composition is $Na_{12}Al_{12}Si_{12}O_{48}$. The structure was first assumed to be cubic with a disordered distribution of Si and Al (*Pm3m* space group), but it became clear that Si and Al alternate in an orderly fashion. This makes it necessary to multiply the unit cell by eight (*Fm3c* space group). An enormous number of fundamentals are expected in both IR and Raman spectra. The strong vibrations expected for the zeolite framework are those above 400 cm^{-1}, whereas the bands in the FIR are essentially due to the vibrations of the Na cations in the cavities.[183] IR spectroscopy has been used extensively for zeolite characterization,[110] and Raman spectroscopy is becoming increasing popular.[184]

6.6.3.3 Glasses Raman and IR spectroscopies are unique techniques for the investigation of the structure of glasses. Many studies have been reported concerning silicate-based glasses,[185] in their anhydrous or hydrated states.[186] Both IR and Raman spectra give information on the nature of Si–OH and $Si-O^- M^+$ terminal bonds with respect to Si–O–Si bridges and of any cyclic structures. The FIR spectra can give information on the coordination state of the cations. Many different compositions have been investigated, such as La aluminosilicates[187] and glasses belonging to the $Li_2O-ZrO_2-SiO_2$ system.[188] Comparisons between the IR spectra of amorphous and crystalline materials belonging to the $MgO-Al_2O_3-SiO_2$ and $Li_2O-Al_2O_3-SiO_2$ systems, including cordierite and β-eucriptite, have also been reported.[189]

6.6.4 Salts with Condensed Octahedral-like Oxo Anions

Chains of oxo anions can condense, giving rise to octahedral-like chains or multiple chains. This is the case for several metavanadates forming double chains $[(V_2O_6)^{2-}]_n$, such as Mg metavanadate. The structure of this compound is shown in Figure 13. In this case vibrational features appear due to triply-bridging O atoms and to pairs of short divanadyl VO_2 bonds.[164] Similarly orthotungstate ions, such as those of metal tungstates in the wolframite structure, condense giving rise to single chains of corner-sharing octahedra (Figure 14). Correspondingly, the spectra can be interpreted in terms

Figure 11 (a) FT/Raman and (b) FTIR and FT/FIR spectra of HZSM5 zeolite.

of bridging W−O−W oxygens and of pairs of diwolframyl WO_2 terminal groups.[153]

6.7 Other Inorganic Materials

6.7.1 Elementary Network Solids

Diamond, silicon, and germanium are elementary solids. They crystallize in the diamond cubic structure, space group O_h^7, $Fd3m$, with $Z = 2$. Consequently, only one triply-degenerate mode occurs which is Raman active. No IR-active fundamentals occur. However, overtones or impurity features can be detectable. Moreover, the Raman-active fundamental appears sometimes to gain some IR activity. For diamond, the fundamental Raman mode was determined as early as in 1930 to be at $1332.5\,cm^{-1}$,[190] but tends to shift down to $1320\,cm^{-1}$ in powders of small particle size.[191] Photoacoustic spectra of diamond allow the detection of adsorbed hydrogen and oxygen.[192] In the case of silicon monocrystals the Raman peak is at $520\,cm^{-1}$[193] and is strongly broadened for amorphous silicon powder. IR spectroscopy is applied to detect and quantify oxygen,[194] hydrogen,[195] and carbon[196] impurities in or on silicon, by measuring the intensities of the Si−O, Si−H, and Si−C IR-active stretching mode. Fundamental TO modes of Ge and cubic Sn fall near $300\,cm^{-1}$ and near $200\,cm^{-1}$, respectively. Raman spectroscopy has also enabled the characterization of tetragonal Ge nanoparticles.[197]

Pure elementary carbon can crystallize in the form of graphite. The vibrational structure has been determined by Fateley et al.[3] in terms of the space group C_{6v}^4, $P6_3mc$

Figure 12 FTIR and FT/FIR spectrum of NaX zeolite.

with $Z = 4$. Due to its conducting behavior, it might not be expected to give either Raman or IR spectra. However, it is reported to give a strong Raman peak at 1580 cm^{-1} and no IR bands.[198] This is consistent with the vibrational analysis performed by Fateley et al.[3] assuming that the interaction between the layers is extremely weak and that the vibrational modes of different layers do not couple.

Vibrational and, in particular, Raman spectroscopy have also been successfully applied to glassy carbon,[199] diamite and carbon nanotubes,[200,201] fullerenes,[202] and metal fullerides.[203] In all cases the strongest Raman peaks fall in the region 1600–1300 cm^{-1}, characterizing a C–C stretching with a bond order intermediate between 1 and 2.

6.7.2 Binary Semiconductors

Most of group III–V semiconductors (cubic BN, and B, Al, Ga, and In phosphides, arsenides and antimonides) crystallize in the cubic zinc blende (sphalerite) structure ZnS (T_d^2, $F\bar{4}3m$) with $Z = 1$. This structure is also taken by β-SiC. This is a superstructure of the diamond structure. In this case there is only one triply-degenerate optical mode that is both IR and Raman active. Accordingly, this mode is polar and undergoes LO/TO splitting (see above) so that two peaks occur in the IR and Raman spectra. The position of the TO mode is sensitive to the weight of the atoms involved. It is found at 795 cm^{-1} for SiC and at 830 cm^{-1} for BP. For heavier atoms down it appears in the FIR region at 400–100 cm^{-1}.[204,205] These materials are therefore useful for windows for the medium IR. The IR reflection spectra allow determination of the composition of semiconducting solid solutions, such as $Al_xGa_{1-x}As$ and $In_xGa_{1-x}As$.[206]

Most group II–VI semiconductors take the hexagonal wurtzite structure, C_{6v}^4, $P6_3c/m$, as does one of the polymorphs of ZnS (wurtzite), ZnO, ZnSe, ZnTe, CdS, and CdSe. This structure is also taken by the nitrides of Al, Ga, In, and Tl, and by α-SiC. The vibrational structure is more complex here, with two Raman-active modes (E_2), two modes both IR and Raman active ($A_1 + E_1$) and one inactive mode (B_1) being expected.

6.7.3 Nonoxide Ceramics

Raman and IR spectroscopies are widely used to investigate nonconducting nonoxide ceramic materials. Aluminum nitride takes the wurtzite-type structure. The active modes have been found by Raman spectrometry to lie at 252 (E_2), 614 (A_1,TO), 660 (E_2), 673 (E_1,TO), 893 (A_1,LO), and 916 cm^{-1} (E_1,LO).[207] IR spectroscopy enables distinction between the polymorphs of silicon nitride, namely α-Si_3N_4, β-Si_3N_4,[208] and amorphous phases.[209]

The materials β-Si_3N_4 and β-Ge_3N_4 crystallize in the hexagonal C_{6h}^2 ($P6_3/m$) space group with $Z = 2$; their IR spectra show that Si–N–Si asymmetric stretchings fall in the region 1100–900 cm^{-1}, whereas Ge–N–Ge asymmetric stretchings fall in the region 920–800 cm^{-1}.[210] The substitutional solid solutions of Al and oxygen into β-Si_3N_4 give rise to "β'-sialons" (Si-Al oxynitrides). This substitution gives rise to broadening and shifts of the

IR absorption bands, allowing the determination of their composition.[211] The vibrational spectra of silicon oxynitride Si_2ON_2, where an oxygen bridge forms between SiN_3 units, has been the subject of skeletal vibrational studies[212] and lattice dynamics calculations.[213]

Boron nitride takes the zinc-blende diamond-like structure with tetrahedrally coordinated B and N atoms or, alternatively, a hexagonal graphite-like structure (h-BN, D_{6h}^4 space group). In this case both types of atoms have trigonal coordination. Two B–N stretching modes are detectable, one IR active and the other Raman active (1366 and 1373 cm^{-1}, respectively), characterizing the vibrations of BN_3 planar units.[214] A turbostratic sample shows vibrational features close to those of h-BN.[215] Raman and IR spectroscopies have recently been applied to the study of stresses undergone by ceramic materials such as Al and Si nitrides.[216,217] The antibixbyite compounds α-Ca_3N_2 and Mg_3N_2 have been the subject of a recent study.[218]

The material β-SiC takes the cubic zinc-blende structure. The splitting of the sole optical mode gives the transverse mode at 796 cm^{-1} and the longitudinal mode at 972 cm^{-1}, detectable both by IR and Raman.[219] The wurtzite structure is adopted by α-SiC, and other polymorphs present highest frequency fundamentals in similar frequency ranges.[220] IR spectra enable the detection of hydrogen and oxygen impurities in these materials.[221] The vibrational spectra of boron carbide $B_{13}C_2$ have also been investigated.[222]

6.7.4 Halides and Sulfides

The halides of most alkali metals take the rock-salt structure, which is Raman silent with only one triply-degenerate IR-active mode (see Table 1). The maximum of the transverse mode is located below 400 cm^{-1} in all cases[204] and shifts to lower frequencies on increasing the weight of either anion or cation. The CsCl structure taken by Cs and Tl^I halides (space group $Pm3m = O_h^1$ space group) also gives rise to only one triply-degenerate IR mode which is located (according to the relevant weight of the cations involved) in the FIR. This makes

both NaCl-type and CsCl-type halides useful materials for windows for the medium IR region. Several halides of divalent metals take the rutile structure (some slightly distorted), or the CdI_2 structure which is strongly related to the brucite structure of $MgCl_2$. Fluorite CaF_2 ($Fm3m = O_h^5$ space group, $Z = 4$) is largely used as a window material for IR due to its nonsolubility in water. The halides of Ba and Pb(II) crystallize in the $Pbnm = D_{2h}^{16}$ space group with $Z = 4$. Their IR spectra are quite complex.[223] However, alkaline earth halides absorb IR at higher frequencies than the corresponding alkali metal halides (the highest frequency IR absorption maximum is at 410 cm^{-1} for CaF_2 and at 465 cm^{-1} for rutile-type MgF_2).

Sulfur is heavier than oxygen, hence vibrational modes involving metal–sulfur bonds fall at lower frequencies than for the corresponding metal–oxygen bonds. Bivalent metal chalcogenides constitute the group II–VI class of semiconductors, taking either the zinc-blende or the wurtzite structures (see above). The position of the fundamental modes of zinc chalcogenides decreases by increasing the chalcogen weight.[204] The fundamental modes of Ca, Sr, and Ba sulfides[224] and Zn and Cd chalcogenides[225,226] fall in the FIR region (below 400 cm^{-1}). Rare earth sesquisulfides have been the object of recent Raman investigations.[227,228] The sulfides of tetravalent Mo and W have a well-known layered structure, but they can also be prepared in fullerene-like and nanotube-like forms. These MoS_2 and WS_2 polymorphic forms have been characterized by Raman spectroscopy.[229] The spectra of several sulfide and chalcogenide structures have been reported and discussed.[81–85]

6.8 Unusual Applications

The application of vibrational spectroscopies to different fields of inorganic materials research is expanding. Among the many interesting and unusual applications are Raman spectroscopic sensors for in situ mineral characterization on planetary surfaces,[230] the study of decorated stained glass[231] to characterize historic pigments[232] such as those used in native American Indian rock art[233] and by Romans,[234] and determination of the composition of medieval pottery fragments from the south of Italy.[235]

Vibrational techniques are used in the characterization of minerals and hydrated products[236] of construction cement, ferroelectric and ferroelastic materials,[237–239] nonlinear optical materials,[240] in petrography,[241] and the analysis of soils.[242] Raman techniques have been applied in ceramics science for the analysis of polymorphs of silicate materials[243] and their thermal expansion properties.[244] FIR is used to characterize dielectric ceramics for microwave applications.[245] Vibrational spectroscopies are used to characterize solid catalysts,[246] and to investigate inorganic materials of biological and medical interest, such as urinary stones[247] and hydroxyapatite.[248]

This introduction opens by discussing the distinction between kinetic and thermodynamic determinations. After defining equilibrium, pseudo-equilibrium, and dynamic measurements, a historical perspective is given that covers early tests and publications to the present overall scope of kinetic determinations. In closing, a listing of selected bibliography is presented; this follows a short narrative emphasizing that kinetics goes beyond determinations in analytical chemistry.

1 EQUILIBRIUM AND KINETIC DETERMINATIONS

The two pillars of the physical sciences are their kinetic and equilibrium components.

1.1 Comparison of Thermodynamic and Dynamic Measurements

All physical and chemical processes, once triggered, evolve to equilibrium by a pre-equilibrium evolution defined as the kinetics of the processes. Practically, however, nothing in this world is perfectly static. Physical and chemical processes do not abide; they occur. Physics and chemistry are scientific disciplines focused on changes that take place in time. Changes occur even in systems considered to be at equilibrium. For all practical purposes, however, the chemical composition of a system and its physical properties remain constant once the system has reached equilibrium, but both change with time during the dynamic evolution to equilibrium.

The rate of transient physical processes as well as the rate of chemical changes can both be used for quantitative analytical purposes. Kinetic determinations based on fluorescence or phosphorescence, for instance, involve primarily physical processes. The bulk of analytical applications based on measurements during transient processes, however, exploit chemical changes. Consequently, this section of this *Encyclopedia* focuses, primarily, on chemical kinetics without neglecting physical processes. Experimentally, measurements of the system composition are possible while reaching equilibrium (kinetic measurements) or with the system at equilibrium (thermodynamic measurements). Consequently, the contemporary analytical chemist can choose to make measurements (e.g. determination of the concentration of a particular analyte) during evolution to equilibrium or at equilibrium. Essentially, kinetic determinations are based on measurements while the composition of the system is changing with time and without disturbing the kinetic process. It is possible, however, to freeze the composition of the system at any given time during the evolution to equilibrium (quenching a given reaction), and to make the 'thermodynamic measurement' at this 'forced equilibrium' situation. Then, relate the composition to the known kinetic behavior of the analyte to arrive at its original concentration in the sample. This practice is seldom used today, but was quite common some years ago, and although technically the measurement is a thermodynamic one, the methodology is classified as resulting in a kinetic determination.

Figure 1 Typical rate–time profile. R_f, rate of forward change; R_r, rate of reversed change. Kinetic (dynamic) measurements are performed in the kinetic region, thermodynamic measurements in the equilibrium region.

The simple formulation, Equation (1):

$$\text{REACTANTS} \longleftrightarrow \text{PRODUCTS} \tag{1}$$

and the corresponding kinetic symbolism, (Equation 2), in which t = time:

$$\frac{dC_{\text{PRODUCTS}}}{dt} = -\frac{dC_{\text{REACTANTS}}}{dt} = \text{rate of reaction} \tag{2}$$

allows the time regions which define kinetic and thermodynamic measurements to be visualized. This is shown in Figure 1.

The rate profile shown in Figure 1 is exhibited by all chemical reactions and physical processes regardless of their complexity. Although the didactic value of this figure is obvious for illustration of the two measurement approaches available for analytical determinations, direct measurement of reaction rates is not practical. What the chemist usually measures directly is some electrical signal, S, related to concentration. In some cases (e.g. conductance or amperometric measurements), S is linearly related to concentration (Equation 3):

$$S = \S C_R \tag{3}$$

in which § is the proportionality constant or transfer function in electrical units per concentration units and C_R represents the concentration of a given reactant at a given time. In some instances, S is not a linear function of C_R (e.g. optical absorption or potentiometric measurements), and the direct instrument response can be written as Equation (4):

$$S = fC_R \tag{4}$$

where f is an arbitrary function. The mathematics is more complicated, generally resulting in nonlinear calibrations.

Table 1 Most common measurement approaches to extract concentration and rate information while the system is evolving to equilibrium

Single point measurements:	Initial rate: derivative, fixed and variable time
	Derivative or $\Delta S/\Delta t$ at $t \neq 0$ (t at which more than 10% reaction has been completed)
Multi point measurements:	Derivative, $\Delta S/\Delta t$, and regression methods
Methods based on kinetic plots:	Method of the tangents

In any event, C_R can always be obtained from S. With a knowledge of concentration and its change with time, reaction rates can then be calculated. Physical changes in the kinetic region are also followed by the change of an electrical signal from which rate information is extracted.

1.2 Approaches to Dynamic Measurement of Concentration

Table 1 summarizes the most important approaches for kinetic determinations based on concentration estimates obtained while the system is evolving to the equilibrium position. An understanding of the operational characteristics of kinetic-based determinations requires a background in the mathematical formulation and manipulation of rate expressions. Most of this background is addressed in detail in several of the articles within this section. In general, however, such a background can be kept simple considering that chemical reactions employed in virtually all kinetic determinations are bimolecular. The analyte species, A, is one of the reactants, and the other reactant, R, is present in large excess rendering pseudo first-order conditions under which:

$$C_{R,\text{ at any time } t} = C_{A,\text{ initial}}e^{-kt} \tag{5}$$

where k = rate proportionality constant (rate coefficient). Equation (5) implies that the initial concentration of analyte can be obtained with a knowledge of S at any given t, k, and § or f, provided the mechanism of the reaction remains constant.

Although the conversion of C_A from S is built into the computer software used with contemporary instrumentation, a knowledge of the value of k often requires independent experimentation. There are, however, experimental/instrumental means that circumvent the need for a knowledge of the value of k. For example, if the value of S is collected only during the initial 1 to 2%, in some cases even 10%,[1] completion of the total process, conditions (e.g. the concentrations of A and R)

remain virtually unchanged, the reversed process can be ignored because $C_{\text{PRODUCT}} \approx 0$, and a pseudo-zero-order process is in operation such as Equation (6):

$$-\left(\frac{dC_{A,\text{ at any time } t}}{dt}\right) \approx k\, C_{A,\text{ initial}} C_{R,\text{ initial}} \approx \text{initial rate} \approx \text{constant} \qquad (6)$$

Equation (6) provides the basis of a very common approach to dynamic measurement of concentration, the initial rate method, since if the initial rate is plotted against $C_{A,\text{ initial}}$ should yield a straight line useful as a calibration plot for the determination of $C_{A,\text{ initial}}$. Three approaches are used to extract initial rate information, they are:

1. the derivative or slope approach, in which electronic differentiation provides dS/dt;
2. the fixed time or constant time approach;
3. the variable time approach.

The fixed time and variable time approaches result from the use of the integral forms of the rate equation, but under conditions such that Equation (6) is approximately valid. The fixed time method involves measurement of a small signal change, ΔS, at a finite but short Δt close to $t = 0$. In the variable time approach, Δt is measured for a finite but small ΔC_R or ΔC_A close to $C_{R,\text{ initial}}$ or $C_{A,\text{ initial}}$. In both cases, the ratio $\Delta S/\Delta t$ gives an approximate estimate of the initial rate.

Initial rate measurements are often recommended because the back reaction does not contribute appreciably to the overall rate, and complications from side reactions are less possible at the beginning of any reaction.

To determine the initial concentration of a desired species, monitoring of the concentration of at least one of the reactants (or products) as a function of time is needed. Continuous measurement of the change in chemical composition is possible by physical, but not by chemical methods, and the observable rates are limited only by the response time of the instruments. With well behaved kinetics and the concentration–time profile obtained by continuous monitoring, two other approaches based on dynamic measurement of concentration can be identified:

1. the derivative approach, and
2. methods based on kinetic plots such as the method of the tangents.

The derivative approach considers that at any time t the value of dS/dt is indicative of the instantaneous rate. If most of the concentration–rate profile is available, relaying on a single derivative (single point measurement) is unwise. This is particularly true now that we enjoy the brute force of the digital computer. The computer makes multipoint-based measurements possible, and this offers two main advantages:

1. less experimental work is needed to seek discriminating variables, and
2. the use of a large number of data points reduces errors.

Table 2 Summary of most common kinetic-based methods

Catalytic methods	• Enzymatic methods employing soluble enzyme preparations • Nonenzymatic catalytic methods
Uncatalyzed reaction-rate methods	• Single-component determinations • Multicomponent determinations (differential reaction rate methods)
Luminescence-based methods	
Determinations in heterogeneous systems	• Kinetic methods based on electrode reactions • Enzymatic methods employing immobilized enzyme preparations

Which approach is used, of those listed in Table 1, primarily depends on available instrumental and/or computational capabilities, and on the type of kinetic method being applied. Table 2 summarizes the main types of methods used in kinetic-based determinations. Except for special cases, all these methods use the measurement approaches listed in Table 1. The measured signal, proportional to concentration, is in all these cases used to derive rate information. The converse approach of estimating the equilibrium concentration (signal) from signals measured under dynamic conditions is less often used. This approach characterizes the so-called predictive methods.[2] Predictive methods are of relatively recent application for kinetic-based determination, but their foundation can be traced back to considerations advanced in 1926 by Christie Smith.[3]

Some approaches to mixing[4] (e.g. centrifugal mixing or continuous-flow mixing) also provide unique means for measurements under dynamic conditions. Unsegmented continuous-flow mixing of the type encountered in the approach commonly known as 'flow injection analysis' provides, in its simplest and most commonly used form, fixed-time measurements under dynamic conditions.[5] Programmed continuous-stopped-continuous-flow procedures in unsegmented systems provide another avenue for signal measurement under dynamic conditions[5] of utility for kinetic-based determinations.

1.3 Equilibrium and Pseudo-equilibrium Measurements to Support Kinetic-based Determinations

The progress to equilibrium of any process can be terminated by quenching the reaction. Quenching is possible by several means, including rapid cooling, precipitation of one reactant, addition of free radical scavengers, or addition of a complexing agent or other chemical species that renders inactive one of the reactants. Quenching by adding an acid or a base can be used, for example, to stop most enzyme-catalyzed reactions. Since the progress to equilibrium has been interrupted, for all practical purposes Equation (7) is valid:

$$-\frac{dC_{REACTANTS}}{dt} = \frac{dC_{PRODUCTS}}{dt} = 0 \qquad (7)$$

and the system, composition-wise, is at 'equilibrium', and therefore the measurement of S is not performed under dynamic conditions. The corresponding values of S, however, can be used to calculate concentrations at given times and apply, for example, the fixed-time or variable-time approach to effect a kinetic-based determination. In such cases one of the times or one of the concentration values may be equal to zero. The speed of today's signal detection/manipulation devices has practically made obsolete quenching for kinetic-based determinations, but quenching is always an approach available to the analytical chemist.

A unique steady-state situation (pseudo-equilibrium condition) is imposed on a system by stat procedures.[6] These procedures are an example of kinetic-based determinations in which a solution containing a chemical species capable of counteracting a chemical change in the system is added to the system. If the rate of delivery matches the rate of change in the system, a steady state situation is approached (stat condition) in which $dS/dt = 0$. The rate for restoring the value of S serves to deduce quantitative information for determinative purposes. This approach has its origins in the determination of enzyme activity with the maintenance of pH at about a constant value (generally the optimum pH for the enzyme) by a pH-stat procedure, but its report in the literature for other type of kinetic-based determinations is scarce.

2 HISTORICAL PERSPECTIVE

Difficult as it is to establish historical priorities, events that left a historical mark – e.g. journal papers and books – can be recognized.

Historically, equilibrium-based determinations predated kinetic-based ones, and they dominated the arena of chemical analysis for a long period of time. During this dominance, kinetics was considered mainly in the context of undesirable effects (e.g. the sluggishness of attainment of some end-points in redox titrimetry). In chemical analysis, the presence of kinetic concepts was very limited in those years, although an outstanding example of positive consideration was present in the recognition that the rate of crystal growth greatly influences the filterability and purity of a precipitate. Precipitation from homogeneous solution,[7] an ingenious application of chemical kinetics, seems to date back to 1858 with the work of Chancel[8] on the separation of iron and aluminum employing thiosulfate.

Difficult as it is to establish historical priorities, a few examples can be cited and are included in the following section.

2.1 Early Tests and Publications

Nonenzymatic catalysis seems to provide the first recorded analytical development of a kinetic-based method. As early as 1876, Guyard (who was also known by the alias Hugo Hamm) discussed the catalytic effect of vanadium on the perchlorate ion oxidation of aniline to yield aniline black and proposed the use of this reaction to detect the presence of vanadium.[9] A decade later, Osmond[10] described a semiquantitative estimation of vanadium by considering that the amount of aniline black formed after a given, fixed, time is proportional to the amount of vanadium present in the sample. The paper was written by Osmond after Georges Witz' death, but was inspired by Witz' studies on certain chemical modifications of cotton, and Witz is listed as coauthor. Oxycellulose threads were dipped into vanadium-containing solutions and subsequently into an aniline–chlorate mixture for a fixed time. The practical minimum detectable quantity can be estimated as 0.000005 mg of vanadium, but the volume of sample used, unfortunately, is not indicated in the publication. This paper is one of the first to report a nonenzymatic quantitative estimation based on a catalytic procedure, and using a fixed time procedure. Osmond also indicates in the same publication that the method was used to recognize the presence or absence of vanadium in samples of different natural mineral waters. In 1881, a few years earlier than the publication of the paper with Witz and Osmond authorship, William Roberts[11] published what can be considered the first application of the variable-time procedure. Roberts was a physician in the Manchester Royal Infirmary and a professor of clinical medicine at Owens College. The procedure proposed by Roberts was inspired by the work of Brown and Heron[12] on the transformation of starch by malt infusions, and the work of Johan Gustaf Kjeldahl on the measurement

of the comparative activity of malt infusions and of saliva at the Carlsberg Institute for research on brewing and the beer industry. Contributions from clinical medicine and industrial enzymology have undoubtedly left an indelible mark in the early history of kinetic-based determinations. Almost half a century passed until catalytic-based determinations were cited again in the records of chemical literature. This time Sandell and Kolthoff[13] introduced the determination of iodide based on its catalytic action on the cerium(IV) oxidation of arsenic(III) by a variable-time procedure. Almost simultaneously, in Hungary, Szebellédy and Ajtai[14] reported a catalytic-based determination of as little as 0.6 ng of vanadium. A large number of determinations based on catalysis have been described since then and many found a place in the first monograph on kinetic methods of determination authored by Yatsimirskii and published in 1966[15] (see Figure 2). A monograph by Arkosi[16] on 'catalytic analysis' preceded by about 10 years the book by Yatsimirskii. Yatsimirskii's book, however, appeared at a time when instrumentation was making measurements under dynamic conditions competitive, and consequently had a significant impact on the development of the topic.

As early as 1921, Clarens[17] applied the laws of chemical kinetics to the dissolved oxygen oxidation of tannins and proposed a fractional determination of tannins in general and in wines in particular. Clarens paper seems to be one of the earliest uses of differential rates for the in situ determination of more than one species in solution. It also points to a pioneering of a kinetic-based approach utilizing uncatalyzed reaction rates. In contrast with catalytic methods, simultaneous determination of more than one chemical species (differential rate methods) are not necessarily aimed at determining low concentrations and most of the reactions employed are uncatalyzed. Relatively more recently, a paper by

Kolthoff and Lee[18] demonstrated that kinetics, via differential reaction rate methods, can give access to medium and major components in a mixture, and thus complementing the accessibility to very low concentrations afforded by catalytic methods. Although the procedure introduced by Kolthoff and Lee, known today as the single-point method, has found infrequent use, it initiated a period extended through the 1950s and 1960s in which differential rate methods drew attention, mainly for the determination of organic species. Lee's chapter in the series 'Organic Analysis'[19] and the book by Fritz and Hammond[20] on quantitative organic analysis emphasize the impact of simultaneous determination of more than one organic chemical in a mixture exploiting rate differences. The chapter by Lee[19] offered the interesting forecast that enzymes would find a place in analytical chemistry as purity of preparations and commercial availability would make them attractive in kinetic-based methodology. Time has proved Lee's forecast as true. Stetter,[21] however, provided one of the earliest documentations of the use of impure enzyme preparations in a variety of analytical procedures.

2.2 From Timers and Watches to Semi-automated and Automated Reaction Rate Methodology

Mixing and timing have been the two experimental operations critical for the development of kinetic methods. Manual mixing (Figure 3) and watches provided the earliest means for implementing such experimental operations, and their crude performance did little to favor the use of kinetics in analytical determinations.

Resistance to accept kinetic-based determinations persisted throughout the 1950s; the main arguments being that time was an elusive variable to measure and/or that concentration was difficult to ascertain at given times if the system was evolving to equilibrium. The 1960s, however, brought accessibility to electronic devices, particularly the use of operational amplifiers, that demonstrated as possible the accurate and precise measurement of signals during evolution to equilibrium: both time and concentration could be reliably known simultaneously. The road to automation of reaction-rate methodology was opened in the 1960s (see Mottola, Kinetic Aspects of Analytical Chemistry, 8–11) and worth mentioning for their pioneering nature are the papers by Malmstadt and Hicks[23] and Blaedel and Hicks.[24] Undoubtedly, the use of strip-chart recorders played an important role in the late 1950s and early 1960s, allowing the recording of signal change with time in relatively slow chemical changes. Figure 4, taken from Yatsimirskii's book illustrates the use of such read-out devices.

Figure 3 A container designed by L.I. Budarin to aid manual mixing of reactants. The container had three compartments for three different solutions, and could be immersed into a water bath for temperature control. When the desired temperature was reached, the container was turned upside down and the contents energetically mixed. Time measurement was started when the container was turned upside down. This type of container was used by Bontchev et al.,[22] for example, to determine silver in human saliva by a catalytic method. (Reproduced by permission of Pergamon Press from K.B. Yatsimirskii, 'Kinetic Methods of Analysis', Oxford, 30, 1966.)

Malmstadt and Hicks[23] reported on how to assemble, from commercially available units and interface it with a controller, an instrument that greatly facilitated the rate-based enzymatic determination of glucose in clinical samples. Blaedel and Hicks[24] introduced the first unsegmented continuous-flow sample/reagent(s) processing system for the continuous measurement of the rate of an enzyme-catalyzed reaction.

The logical next historical development in kinetic-based determinations was a spin-off from electronics: the exploitation of computers for feedback/feedforward control of instrumentation, signal collection and manipulation, and data treatment (e.g. application of multipoint

regression, Kalman filtering, predictive approaches, and simulations *to name a few, and which are covered in other sections*). These, however, take us too close to today's developments and away from the historical roots that pertain to this article. The interfacing of a general purpose digital computer for on-line processing of reaction rate data, for example, dates back to the late 1960s.[25]

2.3 From Determination of Inorganic Species to the Determination of Organic and Biochemicals

The developments in the field of kinetic-based determinations have paralleled the evolution experienced by chemical analysis throughout the years. During the years in which thermodynamic-based measurements dominated the analytical subdiscipline of chemistry, the attention was focused on what can be called 'mineral analysis'. In those years then, the focus was on the determination of inorganic species. Catalytic determinations, which opened the road to measurements under dynamic conditions, did not escape such an influence, and most of the early catalytic determinations were of inorganic species. Therefore, is not surprising to find a few catalytic determinations cited as part of 'inorganic microchemistry' in some early reviews.[26] More than half of the citations in these reviews, however, reported the use of organic reagents for equilibrium-based measurements aimed at the determination of inorganic species, a 'hot' topic at the time. In the middle to late 1940s, the need for training inorganic chemistry for analytical chemists became more widely recognized. This is perhaps best summarized in the following words lifted from the Preface of a timely book on functional analysis by Siggia:[27]

> I recognize the great need which exists in our colleges and universities for formal training in the field of quantitative organic analysis, and I know that very few schools offer this training ... chemists are needed who are trained to do analytical work with compounds of this type. It is my belief that quantitative organic analysis should be included in the regular analytical courses that are usually entirely inorganic.

These were the times when elemental analysis data was beginning to be supplemented with information extracted from functional group analysis based on acid–base and redox titrimetry as well as on the measurement of gases consumed or liberated by reactions of analyte and reagents. In parallel, instrumental techniques such as chromatography, electrophoresis, polarimetry, light absorption, and polarography – to name a few making an impact at that time – were helping to blur the inorganic prevalence. Kinetic-based analytical methods backed the trend in the 1950s and 1960s which can be considered to be triggered by Kolthoff and Lee's paper introducing the single point method.[18] Statements such as those by Fritz and Hammond[20] in their book on quantitative organic analysis (page 167):

> It is the opinion of the authors that the analyses described in which the differential kinetic procedure was used could not have been solved by any other method of comparable simplicity.

as well as that of Lee forecasting the impact of enzymes on analytical chemistry,[19] accurately framed the position of kinetic-based determinations paralleling the evolution of analytical chemistry itself (page 242):

> There is no doubt that methods based on catalysis by enzymes will increase in number and practicability as advances are made in the study of these substances and as more enzymes of known activity and purity become commercially available.

Transition from inorganic to organic and to biochemical analysis was paved at that time and kinetic-based measurements played an important role in such transition.

3 KINETICS IN ANALYTICAL CHEMISTRY: BEYOND DETERMINATIONS

Many analytical techniques or approaches, if scrutinized closely, are perceived to be of kinetic nature or to involve key kinetic components.

Chemical reactions in solution provided the early foundation and constitute an important portion of the subdiscipline we know today as analytical chemistry. Equally important, however, is the realization that many analytical methods and techniques are solely based on the measurement of a physical property of the system or chemical species of interest. In either case – whether a reaction-based or a physically-based measurement – measurements under dynamic conditions can not only generate information useful for determination of chemical species, but also for the fundamental understanding of the process(es) involved. In the realm of analytical chemistry, the relevance of kinetics goes beyond determinations.

3.1 Chemical Reactions and Physical Processes in Analytical Chemistry

The bulk of analytical chemistry based on chemical reactions focus on solution chemistry, particularly with water as solvent. Traditionally, four basic types of reactions have been used, and they still continue to be used, in both equilibrium-based and kinetic-based methods. They are:

1. precipitation (ion-exchange reactions),
2. acid–base (proton-exchange reactions),
3. redox (electron-exchange reactions), and
4. complexation (ligand-exchange reactions).

In kinetic-based methods, proton transfer and precipitation reactions have had very limited use. On the other hand, redox reactions dominated applications based on nonenzymatic catalytic determinations, and ligand exchange reactions have been frequently used in the development of differential rate methods.

Although not as easily recognized, rates of change of physical properties of a system play important roles in contemporary analytical chemistry. The rate of mass transfer is a case at hand. Diffusion and convection as time-dependent processes, for example, are particularly critical in electroanalytical chemistry, separations, and continuous-flow procedures. In the field of spectroscopy, excitation–absorption–emission are all rate driven processes critical in atomic as well as molecular spectroscopy.

3.2 Some Areas of Analytical Chemistry in which Kinetics Play a Direct or Indirect Role

Although the theme of this Encyclopedia is focused on determinations and instrumentation, a few words about other roles of kinetics in analytical chemistry are in order. Practically, in all areas of interest to analytical chemistry, kinetics play an important direct or indirect role. This is because time-dependent chemical and physical processes are ingrown into most aspects of analytical chemistry. This is true from very classical methodologies (e.g. gravimetric analysis) to rather recent tools (e.g. glow discharge optical emission spectroscopy and cavity ring-down laser absorption spectroscopy). The theoretical aspects of precipitation are derived from theories on nucleation and crystal growth.[28] Kinetics is of interest in many separation approaches such as solvent extraction (for example in metal ion separation[29]), ion exchange,[30] and chromatography in general.[31] Both the rate of electron transfer at the electrode/solution interface and chemical kinetics in and in the vicinity of the double layer are of paramount importance in electroanalytical chemistry.[32]

Direct injection enthalpimetry is one of the thermal methods in which kinetics is most obvious since it is based on monitoring the change in temperature with time.[33] Other thermal methods reveal kinetic in their theoretical foundations such as it is the case in differential thermal analysis.[34] Continuous-flow sample/reagent(s) processing for the so-called 'wet chemistry' are all approaches plentiful in kinetics.[5,35]

The enumeration of analytical approaches rich in kinetics becomes almost endless, including for example typical spectroscopic (e.g. nuclear magnetic resonance) and non-spectroscopic methods (e.g. mass spectrometry), but before calling to a close this section a mentioning of some well established spectroscopic approaches (e.g. absorbance-based measurements and luminescence-based methods) as well as some not so popularized as yet (e.g. glow discharge emission and cavity ring-down absorptiometric measurements) is pertinent. The kinetic nature of fluorescence and phosphorescence is well established,[36] and even one of the distinctive aspects that distinguish phosphorescence from fluorescence is rate related, i.e. the decay periods are much longer in phosphorescence because relaxation from the triplet to the ground state singlet is forbidden by spin symmetry.[37]

Bioluminescence is a special case of chemiluminescence in which the chemical reaction responsible for photon emission occurs or can occur in nature. Both, however, are observed when an electronically excited product is produced that either luminesces or transfers its excess energy to another molecule that then luminesces. Kinetically, such situations result in series processes

leading to transient signals and which can be symbolized as Equations (8–11):

$$A + B \longrightarrow C^* \quad (8)$$

$$C^* \longrightarrow C + h\nu \quad (9)$$

or

$$C^* + D \longrightarrow D^* + C \quad (10)$$

$$D^* \longrightarrow D + h\nu \quad \text{or} \quad D' + h\nu \quad (11)$$

A free energy change of at least 44 kcal mol^{-1} is required for emission of light in the visible region of the spectrum. This is usually provided by redox reactions involving oxidants such as O_2 and H_2O_2 and cyclic hydrazides (e.g. luminol or acridine derivatives).[38] Temporal resolution of events in the picosecond and even femtosecond range is of interest in analytical detection, particularly in time-resolved spectroscopic measurements.[39]

Kinetics is not only prominent in well established spectroscopic techniques. Rather recent additions to the spectroscopic tool chest are successful because of critical kinetic components, or because the measurement approach itself is kinetic in nature. In glow discharge optical emission spectroscopy,[40] for example, signals are directly related to the supply rate of element into the plasma. In the so-called cavity ring-down spectroscopy,[41] the measurement of photon absorption is based on a time measurement: the time for the detected photomultiplier response (signal) to decay to $1/e$ of its original value.

Reviews and Other Useful Publications

General

1964–Present: Biennial reviews (Fundamental Reviews) in the journal Analytical Chemistry. This series started in 1964 with a review entitled 'Kinetic Aspects of Analytical Chemistry', authored by G.A. Rechnitz, and since then has appeared every two years with occasional change in authors.

H.L. Pardue, 'Holistic View of Chemical Analysis with Emphasis on Kinetic Methods', *Quim. Anal. (Bellaterra)*, **II**, (Extra), 24–34 (1983).

H.L. Pardue, 'Unified View of Kinetic-based Analytical Methods with Emphasis on Ruggedness', *Analyst*, **121**, 385–390 (1996).

Accounts of Evolution in Kinetic Determinations

H.A. Mottola, 'An Account of Kinetic Determinations and Other Kinetic Aspects of Analytical Chemistry: From Córdoba to Erlangen', *Analyst*, **118**, 675–679 (1993).

H.A. Mottola, 'From Erlangen to Moscow: Minor Redirections', *Analyst*, **121**, 381–383 (1996).

Definitions, Nomenclature, and Related Topics

H.B. Mark, Jr, 'Development and Publication of New Methods in Kinetic Analysis', *Talanta*, **20**, 257–266 (1973). [Recommendations made regarding research for development of new methods and/applications. Presentation of the results for publication also discussed].

Although a catalyst does not shift the position of equilibrium but it does markedly change the reaction rate, because the catalyst lowers the activation energy of a reaction providing an alternative favorable route for the formation of the products. The reacted catalyst is regenerated and is repeatedly involved in an indicator reaction. When the rate depends on the concentration of the catalyst, it can be determined by measuring the change in the physical properties of the reactants and/or products in the indicator reaction. The change in a physical property such as absorbance, fluorescence, chemiluminescence (CL) or electrode potential of a reaction system is usually monitored with time. This methodology is called catalytic methods or kinetic–catalytic methods of analysis.

Kinetic–catalytic methods of analysis based on catalyzed reactions have progressed recently and have been applied to trace analyses for various catalysts (element) because of their extremely high sensitivity, low limit of detection and selectivity. Several reactions such as redox, ligand substitution and complexation reactions have been utilized as indicator reactions for the development of kinetic–catalytic methods of trace analyses. Most of the catalysts in redox reactions are metal ions or inorganic anions having different oxidation states such as cobalt, copper, chromium, iron, manganese, vanadium, selenium, iodide, bromide and nitrite. Oxidants capable of regenerating the catalyst are hydrogen peroxide, chlorate, bromate, periodate and dissolved oxygen. Reductants include ascorbic acid, hydroxylamine, hypophosphorous acid, alkali sulfides, dithiothreitol and tin(II).

Certain substances significantly increase the rate of catalyzed reactions. These substances are referred to as activators and have been defined as substances that do not catalyze the indicator reaction but enhance the catalytic effect of the catalyst. Activators provide high sensitivity and selectivity in kinetic–catalytic methods. Such improved specificity can be expected to eliminate the preliminary separation in many instances.

As the measurement includes time as an experimental variable, care is needed to ensure that mixing of reagents takes place at regular time intervals to obtain highly accurate results using a manual procedure. Such disadvantages in the manual system can be overcome by using flow-injection analysis (FIA), in which the reaction time can easily be controlled by varying the flow rate of the solutions and the length of the reaction coil.

Kinetic–catalytic methods allow the determination of various elements at nanogram and picogram levels (10^{-11} M) with a simple and reasonable equipment. The detection limits (DLs) of the methods are of the order of picograms per milliliter with good accuracy and precision and are almost equal to those for inductively coupled plasma mass spectrometry (ICPMS).

The application of catalytic effects of metal ions in titrimetry has been recognized for a long time. This methodology is called catalytic titration and involves two

consecutive reactions, i.e. titration reaction and indicator reaction. The determinable concentration is almost 10^{-6} M of the metal ions.

1 INTRODUCTION

Methods of chemical analysis for the analyte in a mixture are mainly classified into two classes, *thermodynamic* (or *static*) and *kinetic* (or *dynamic*) classes, according to the nature of measurement employed. A thermodynamic method generally involves changing the equilibrium conditions of the reaction system to proceed essentially to completion, that is, the equilibrium greatly favors the reaction products, and a physical property of the solution, corresponding to the concentration of either the reactants or the products, is measured by using conventional analytical methods such as spectrophotometry, fluorometry, chemiluminescent method, atomic absorption spectrometry, flame spectrometry, an electrochemical method, and so on. A kinetic method involves the measurement of the rate of the chemical reaction under nonequilibrium conditions as a function of time. Furthermore, kinetic methods of analysis are classified into two categories, catalytic and noncatalytic determinations. These methods have been subdivided according to the type of reaction and to the procedure employed for determining single or multiple components in a mixture. Classification of kinetic methods is listed in Table 1.

The change in a physical property such as absorbance, fluorescence, CL, electrode potential of a system is usually monitored. Numerous batch and flow-injection methods have been reported for the catalytic determination of trace elements. Kinetic–catalytic methods are usually much more sensitive than thermodynamic ones based on stoichiometric reactions. The sensitivity of the kinetic–catalytic methods of analysis is estimated to be 10^{-16} M or 10^{-5} pg mL^{-1}, under the most suitable conditions, when a spectrophotometric method is used for determining reaction rate.[1] The use of activators in the kinetic–catalytic methods increases further the sensitivity and selectivity of the methods. Improved specificity can be expected to eliminate the preliminary separation in many instances. The details of the action of activators will be discussed in section 4.

Table 1 Classification of kinetic methods based on the type of reaction employed

Catalytic methods
Nonenzymatic: catalytic effects of chemical species on redox and ligand substitution reactions
Enzymatic: substrate determinations employing soluble and immobilized enzymes
Electrochemical: electrode reaction
Noncatalytic methods
Determination of a single species
Determination of multicomponents (differential reaction rate methods)

A catalytic reaction was first applied to quantitative analysis by Guyard who reported a catalytic determination of vanadium based on its catalytic effect on the oxidation of aniline by chlorate in 1876.[2] Nearly 60 years later, Sandell and Kolthoff reported the iodide determination using its catalysis on the reaction of As(III) with Ce(IV),[3,4] Equation (1)

$$\text{As(III)} + 2\text{Ce(IV)} \longrightarrow \text{As(V)} + 2\text{Ce(III)} \qquad (1)$$

This method is probably the only catalytic method for iodine as iodide that has been extensively used. After that, kinetic–catalytic methods have been recognized as offering a valuable approach to trace analysis, because of their high sensitivity, low limit of detection and good selectivity, and have been the subject of reviews[5–23] and monographs.[24–27] Since 1964, biennial reviews entitled ''Kinetic Determinations and Some Kinetic Aspects of Analytical Chemistry'' have been published in *Analytical Chemistry*.[28–34] The contents of the reviews consist of kinetic methods for determination of catalyst, kinetic methods based on activation or inhibition of catalysis, titrimetric methods with catalytic end-point indication, kinetics and mechanisms of some catalyzed reactions of analytical interest, applications of luminescence, kinetic methods based on uncatalyzed reactions, differential methods (simultaneous multicomponent determinations), instrumentation, and so on. According to Mottola, the idea of an international gathering of chemists interested in all kinetic aspects of analytical chemistry was conceived in the late 1970s. Since the First International Symposium on Kinetics in Analytical Chemistry took place in Cordoba, Spain, 1983, a series of symposia has been held every three years.[35–38] The details of many of the contributions presented at these meetings from the second symposium can be found in *The Analyst*.

This article focuses on kinetic–catalytic methods for nonenzymatic reactions in homogeneous systems.

2 THEORETICAL BASES OF KINETIC–CATALYTIC METHODS OF ANALYSIS

A catalyst is a substance that alters the rate of a reaction without being consumed or shifting the position of equilibrium of a reaction system. The catalyst lowers the activation energy of a reaction, providing an alternative favorable route for the formation of the products. Reacted

catalyst is regenerated and repeatedly involved in the reaction, although the catalyst is chemically unchanged at the end of the reaction. The rate of catalyzed reaction is proportional to the concentration of the catalyst under given conditions and can therefore be employed for the catalyst determination by using a suitable procedure.

In the kinetic–catalytic methods, the main reaction in which the species participate is called the indicator reaction. This reaction is always thermodynamically favored to completion, but is kinetically unfavorable. One type of indicator reaction frequently used in the kinetic–catalytic methods is a redox reaction in which the catalyst M, usually a multivalent ion, changes its oxidation state during the reaction as follows, Equations (2–4):

$$S + R \longrightarrow P + Q \quad (2)$$

$$S + M \longrightarrow P + M' \quad (3)$$

$$M' + R \longrightarrow Q + M \quad (4)$$

where S and R are the substrate and reagent, respectively, and P and Q are the reaction products in the indicator reaction, Equation (2). The indicator reaction is usually very slow. However, when an ion M acts as a catalyst, it accelerates the formation of the product P and is then converted into a different oxidation state, M′ by reaction shown in Equation (3). If M′ is regenerated again to M by reaction shown in Equation (4), the formation of P is catalyzed by a trace amount of M. Thus small amounts of M even at subnanogram levels can be determined by measuring the rate of the formation of P. It is also true from Equation (4) that M′ can be determined as well as M.

The rate of reaction (2) catalyzed by M, v, is expressed as Equation (5):

$$v = k_u[S]^a[R]^b + k_c[S]^a[R]^b[M]^c \quad (5)$$

where k_u and k_c are the rate constants of uncatalyzed and catalyzed reactions, respectively, and a, b and c are reaction orders with respect to each species. In most cases, the reaction is first-order in S and R, and also in M. Then rate Equation (5) can be written as:

$$-\frac{d[S]}{dt} = \frac{d[P]}{dt} = k_u[S][R] + k_c[S][R][M] \quad (6)$$

The concentration of the catalyst in a mixture can be determined by monitoring the rate of decrease in concentration of S or the rate of an increase in concentration of one of the products. It is preferable that the rate constant of uncatalyzed reaction, k_u, is smaller than that of catalyzed reaction, $k_c[M]$, in order to obtain high sensitivity and precise results.

3 INDICATOR REACTIONS

A large number of indicator reactions are used for the kinetic–catalytic methods in homogeneous systems. Nonenzymatic indicator reactions can be classified into two broad categories: (1) redox reaction and (2) ligand substitution and complex formation reactions.

3.1 Redox Reactions

Redox reactions have frequently been used as the indicator reactions in kinetic–catalytic methods with spectrophotometric detection. Reactant S used in the redox reaction is an inorganic or organic compound, which is converted into a colored or colorless compound P by an oxidant and/or a reductant R. Oxidation reactions of organic compounds are likely to be used most frequently as the indicator reactions for the determination of metal ions based on their catalysis. The absorbance change of the reactant S and/or the product P is usually monitored. Typical organic compounds used in the indicator reactions are presented in Figure 1. Oxidants used in the indicator reactions are hydrogen peroxide, chlorate, bromate, peroxodisulfate, periodate and dissolved oxygen, and reductants such as ascorbic acid, hydrazine, hydroxylamine, hypophosphorous acid, alkali sulfides, thiosulfate and tin(II), etc. are also used. The role of oxidants is simply to regenerate the catalyst M. Although these oxidants have high oxidation potential for oxidizing S to P, the oxidation rate is very slow, and the regeneration process of M′ to M proceeds very rapidly. The concentration of catalyst M is kept constant during the reaction, as a result of the regeneration of M. Thus a trace amount of M can be determined. Typical examples of catalysts are metal ions such as iron(II, III), copper(I, II), manganese(II, IV, VII), vanadium(IV, V), cobalt(II, III), chromium(III, VI) and nonmetal ions such as iodide and bromide.

CL processes are closely related to redox reactions. Generally, CL is observed in a redox reaction which yields an electronically excited product; it emits luminescence or transfers its energy to another luminescent molecule present.[39,40] As shown in Figure 2, commonly used reagents for the CL reactions are acyl hydrazides (e.g. luminol), acridine derivatives (e.g. lucigenin), imidazoles (e.g. lophine) and peroxyoxalates (e.g. bis(2,4,6-trichlorophenyl) oxalate (TCPO) and bis(2,4-dinitrophenyl) oxalate (DNPO)).

Of these, luminol (5-amino-2,3-dihydro-1,4-phthalazinedione) is widely used in the CL reactions. The CL reaction of luminol was first reported by Albrecht in 1928[41] and involves the oxidation of luminol by oxidants such as oxygen, hydrogen peroxide, hypochlorite, persulfate, and so on in an alkaline solution.[42,43] The CL reaction of luminol with hydrogen peroxide has been

known as one of the most sensitive systems in analytical use and has been applied for the determination of metal ions such as cobalt(II), copper(II), chromium(III), iron(II) and so on, at the nanogram level. In addition, the luminol/H_2O_2/hexacyanoferrate(III) system has been widely used for the determination of hydrogen peroxide and biosubstances.

Lucigenin (10,10′-dimethyl-9,9′-biacridinium dinitrate) is the second most popular CL reagent and its CL properties were first observed by Glue and Petsch in

Figure 1 Representative examples of organic compounds used in indicator reactions. Figure 1 (*Continued*)

Figure 2 Representative CL compounds and their postulated schemes. I, luminol; II, lucigenin; III, lophine; IV, TCPO (F denotes a fluorophore).

1935.[44] The oxidation of lucigenin occurs with peroxide under alkaline media to produce a blue light emission as well as a green luminescent light when a catalyst, e.g. heavy metal ion, is present. This blue light is spectrally the same as the fluorescent light of the oxidized product of lucigenin, *N*-methylacridone.[43] As *N*-methylacridone is insoluble in water, a micellar system containing a suitable surfactant is used to solubilize the precipitate.[45] There are a large number of analytical applications of the CL reaction of lucigenin for the determination of metal ions.

The CL of lophine (2,4,5-triphenylimidazole) was first discovered by Radzisewski in 1877.[46] The CL reaction of lophine involves the initial oxidation of the lophine anion to its free radical, reaction of the radical with molecular oxygen to give a peroxide, and reaction of the peroxide with base to yield light.[47] The oxidation reaction of lophine is also catalyzed by various transition metal ions in the presence of suitable oxidants.

Peroxyoxalate CL involves its oxidation with hydrogen peroxide to produce an energy-rich intermediate. This metastable intermediate can provide enough chemiexcitation energy for the production of an excited state fluorophore. Through the production of a charge transfer complex between the intermediate and a fluorophore, the actual chemiexcitation step occurs. This charge transfer complex dissociates to produce the chemically excited fluorophore which returns to the ground state via emission of a photon.[48]

3.2 Ligand Substitution and Complexation Reactions

Kinetic–catalytic determinations not involving redox reaction processes have also been developed by many authors. An example of this category is the substitution of ligands and/or metal ions in metal complexes. This reaction is homogeneously catalyzed by minute amounts of relatively soft metal ions such as mercury, cadmium as well as ammonia and some other species.

A substitution reaction of one ligand by another L in a metal complex maximum absorbance (MA) or MAX and a double exchange reaction between M_1L and M_2X are widely used in kinetic–catalytic methods, according to the general scheme shown in Equations (7–9):

$$MA + L \longrightarrow ML + A \tag{7}$$

$$MAX + L \longrightarrow ML + A + X \tag{8}$$

$$M_1L + M_2X \longrightarrow M_1X + M_2L \tag{9}$$

An example of Equation (7) is the reaction of hexacyanoferrate(II) with *p*-nitrosodiphenylamine (*p*-NDA) in aqueous solution, which is catalyzed by mercury(II), Equation (10).[49,50]

$$Fe(CN)_6^{4-} + p\text{-NDA} \longrightarrow Fe(CN)_5 \cdot p\text{-NDA}^{3-} + CN^- \tag{10}$$

The concentration of the green product, $[Fe(CN)_5 \cdot p\text{-NDA}]^{3-}$ ($\lambda_{max} = 640$ nm), is proportional to the amount of mercury(II) present in a solution at a fixed time. The determinable range for mercury(II) is 1×10^{-7}–1×10^{-6} M.

An example of Equation (9) is the exchange reaction between triethylenetetraminenickel(II) (NiT^{2+}) and ethylenediaminetetraacetatocuprate(II) (CuY^{2-}), which is catalyzed by EDTA (ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid) or Trien (triethylenetetraamine) and is inhibited by any metal ions complexing these ligands,[51,52] Equation (11)

$$NiT^{2+} + CuY^{2-} \longrightarrow CuT^{2+} + NiY^{2-} \tag{11}$$

The exchange rate is monitored by measuring the absorbance of CuT^{2+} as a function of time. Trace amounts of EDTA (10^{-7} M levels) and metal ions (10^{-8} M levels) can be determined.

4 ACTIVATORS AND SURFACTANTS IN CATALYZED REACTIONS

Generally a catalyzed reaction proceeds more quickly than an uncatalyzed reaction with an increase in temperature and reaction time. However, the increase in temperature and time also increases the rate of uncatalyzed reaction. It is possible to increase the sensitivity of kinetic–catalytic methods by the application of activators and/or surfactants.

4.1 Activators

An activator is defined as a substance that does not catalyze the indicator reaction, Equation (2), but increases its rate in the presence of a catalyst. The use of activators also provides greater selectivity in kinetic–catalytic methods. According to Bontchev,[6] activators are classified into three groups depending on the role of the catalyst in the reaction, the nature of the catalyst–activator interaction and the stage of the reaction affected in the presence of the activator:

1. activators affecting the catalyst–substrate interaction
2. activators participating in the regeneration of the catalyst
3. activators acting indirectly in the catalytic process.

Generally, activation effects are limited to metal-catalyzed reactions and connected to the complex-forming tendency of metal ions. Furthermore, the dependence of the rate of the reaction on activator concentration shows a maximum. Such a maximum is a characteristic feature of all types of activator which are concerned

with the formation of ternary complexes of the type activator–metal–substrate.[6] Thus, the coordination sphere of the catalyst is fully occupied by the activator and any complexation with substrate does not occur at higher concentrations of activator. For example, 1,10-phenanthroline (phen) and 2,2′-bipyridine (bpy) act as effective activators for the catalysis of iron(III),[53] manganese(II)[54] and copper(II)[55] in the indicator reactions and the dependence of the concentration of these activators shows a maximum. 5-Sulfosalycilic acid, tartaric acid and 1,2-dihydroxy-3,5-benzenedisulfonic acid (Tiron) act as effective activators for vanadium(V)-catalyzed reactions.[56,57] EDTA acts as an effective activator only for the chromium(III)-catalyzed reactions,[58] although EDTA masks the catalysis of other metal ions.

4.2 Surfactants

Surfactant molecules associate dynamically to form assemblies such as micelles, reversed micelles and bilayer aggregates (lamela or vesicle structure).[22,59,60] At concentrations above the critical micelle concentration (CMC) of surfacants, the following capabilities are expected:

1. solubilize, concentrate and organize reactants according to hydrophobic, electrostatic and specific interactions
2. alter the effective microenvironment, i.e. polarity, viscosity, acidity
3. alter the chemical pathways and reaction rates
4. alter the spectral parameters of solubilized chemical species
5. stabilize the chemical species with optical transparency.

These properties are of interest in analysis and can be useful in kinetic–catalytic methods as well as in equilibrium-based ones. The use of organized surfactant molecular assemblies increases the sensitivity, selectivity and precision of the methods. For example, the copper(II)-catalyzed reaction between *N*,*N*-dimethyl-*p*-phenylenediamine (DPD) and DMA in the presence of hydrogen peroxide is enhanced by sodium dodecylsulfate (SDS) and dodecyltrimethylammonium bromide (DTAB) micelles.[61] The DL and specificity of the copper(II) determination in the presence of SDS or DTAB are improved compared with those in their absence.[62]

5 METHODS OF DETERMINATION

In order to determine the concentration of a catalyst or a reactant in solution by the kinetic-based method, the change in the physical property of the monitored species as a function of time must be measured and kinetic curves are needed.

The procedures for determining the catalyst concentration by measuring the rate of catalyzed reaction are the initial rate method (tangent method), fixed time method and variable time (fixed concentration) method.[1,24–27] The induction period measurements are also applied to some catalytic reactions in which there is a time delay between reactants and the appearance of change in the chemical composition of the system.

Equation (6) can be simplified as follows, Equations (12) and (13):

$$\frac{\mathrm{d[P]}}{\mathrm{d}t} = F_\mathrm{u} + F_\mathrm{c}[\mathrm{M}] \tag{12}$$

$$\frac{\Delta[\mathrm{P}]}{\Delta t} = F_\mathrm{u} + F_\mathrm{c}[\mathrm{M}] \tag{13}$$

where F_u and F_c are the conditional constants of uncatalyzed and catalyzed reactions, involving the concentrations of the reactants, respectively. These equations are the basis of determining the concentration of the catalyst.

5.1 Tangent and Initial Rate Methods

The rate of a reaction, v, corresponds to the concentration of the catalyst as exemplified by Equation (14)

$$v = \frac{\mathrm{d[P]}}{\mathrm{d}t} = F_\mathrm{u} + F_\mathrm{c}[\mathrm{M}] \tag{14}$$

The change in a physical property of a monitored species is observed continuously and recorded versus time (Figure 3a). The slope of the resulting straight line, $\tan\alpha$, is a measure of the catalyst concentration, known as the tangent method. The plot of $\tan\alpha$ versus the concentration of catalyst is employed as a calibration graph (Figure 3b). The initial rate of the reaction is also measured from the slope of kinetic curves; this approach is called the initial rate method. Although the measurement of the initial rate requires the kinetic curve, it has some advantages:

1. The reaction obeys pseudo-zero order kinetics with respect to the reactants, because these concentrations do not change appreciably.
2. The back reaction which contributes to the rate of overall reaction is virtually nonexistent, because the amount of product formed during the initial period is very small.
3. Complications arising from any side reactions are minimized during this period. Thus, the reproducibility and the selectivity of the initial rate procedure

Figure 3 Absorbance – time curves (a) and calibration curve for catalyst determination by the tangent method (b).

Figure 4 Absorbance – time curves (a) and calibration curve for catalyst determination by the fixed time method (b).

are better than those of a fixed time procedure. In addition, the use of the initial rate as a parameter can be obtained over a wider determinable range, i.e. two or three orders of magnitude.

5.2 Fixed Time Methods

This method involves the determination of a physical property corresponding to the concentration of a reactant or a product at a definite time after the initiation of the reaction. For the fixed-time method, Equation (13) can be rewritten as Equation (15):

$$\Delta[\mathrm{P}] = (F_\mathrm{u} + F_\mathrm{c}[\mathrm{M}])\Delta t \qquad (15)$$

Figure 4(a) shows the kinetic curves in the absence and the presence of the catalyst and Figure 4(b) shows a plot of an absorbance at a fixed time versus the concentration of the catalyst. From the latter curve (calibration curve), the concentration of the catalyst can be determined.

5.3 Variable Time Methods

The time required to attain a constant change in composition may be measured. For the variable time method, Equation (13) can be rewritten as Equation (16):

$$\frac{1}{\Delta t} = \frac{F_u + F_c[M]}{\Delta[P]} \tag{16}$$

From the kinetic curves shown in Figure 5(a), a plot of $1/\Delta t$ as a function of [M] (Figure 5b) is obtained and is used for the determination of the catalyst.

5.4 Measurements of Induction Period

Some reactions used in the catalytic methods are characterized by the occurrence of induction periods. Reactions of this type generally proceed in two or more stages. The product of the first slow stage behaves as reactants for the second and final stages. The concentration of the catalyst is obtained from the following relationships, Equations (17) and (18)

$$[M] = \frac{\text{const}}{t_i} \tag{17}$$

$$[M] = \frac{\text{const}}{t_i^2} \tag{18}$$

where const denotes a conditional constant for a given reaction and t_i is an interval time of an induction period. Figure 6(a) shows typical absorbance versus time curves and Figure 6(b) shows a plot of $1/t_i$ versus catalyst concentrations.

5.5 Analysis of Mixtures by Differential Rates

Differential reaction rate methods, based on the different rate at which two or more species interact with a common reagent, permit analysis of two or more species without prior separation.[63] Although these methods are based on an uncatalyzed reaction, they are also applied to the determination of mixtures acting as catalyst for a given catalyzed reaction. Differential rate methods are classified into two categories depending on the approach used:[26,27]

1. those based on graphical evaluations (e.g. logarithmic extrapolation method), and
2. those based on mathematical complications (e.g. proportional equation method).

An example is the simultaneous determination of Ru and Os based on their catalysis in the reaction of Ce(IV) with As(III).[64] With concentrations of 5×10^{-3} M Ce(IV) and 1×10^{-3} M As(III), conditions prevailing

Figure 5 Absorbance – time curves (a) and calibration curve for catalyst determination by the variable time method (b).

for selectivity for ruthenium, the initial reaction rate of the catalyzed reaction in 2 M H_2SO_4 is given by Equation (19)

$$v_1 = 240[RuO_4] + 90.4[OsO_4] \tag{19}$$

With concentrations of 5×10^{-4} M Ce(IV) and 1×10^{-3} M As(III), the latter being added first, and conditions prevailing for selectivity for osmium, the resulting rate

Figure 6 Absorbance – time curves (a) and calibration curve for catalyst determination by the measurement of induction period (b).

equation is expressed as Equation (20):

$$v_2 = 2.69[RuO_4] + 78.0[OsO_4] \qquad (20)$$

By measuring the rates under these two sets of conditions, mixtures of RuO_4 and OsO_4 in the range 2×10^{-10}–1×10^{-7} M can be determined with relative standard deviations ranging 0.51–4.1%.

5.6 Flow-injection Analysis

Since kinetic methods include time as an experimental variable, care is needed in the mixing of reagents at regular time intervals to obtain highly accurate results. Furthermore, batch methods are sometimes time-consuming and laborious. Such disadvantages in the batch method can be overcome by using FIA, which is firmly established as a fast precise accurate efficient and extremely versatile analytical technique. The FIA method is a suitable technique for catalytic methods of analysis because the rate of the catalyzed reaction can easily be controlled by fixing the flow rate of the solutions and the length of the reaction coil, yielding reproducible mixing. The fundamental characteristic of FIA is its intrinsically kinetic nature. The adaptation of FIA to catalytic methods can lead to many advantages, namely rapid and reproducible mixing of sample and reagents solutions can be achieved in the closed flow system without any contamination from the environment and a large number of samples can be treated automatically in a short time.[65] FIA procedures for trace elements using of kinetic–catalytic methods have been reviewed.[21]

6 TITRIMETRIC METHODS WITH CATALYTIC END-POINT INDICATION

In 1960, Erdey and Buzas[66] first reported the titration of EDTA with copper(II) employing copper(II)-catalyzed luminol and lucigenin CL as indicator reactions which were later studied in depth by Mottola.[67,68] Since the appearance of this work, papers on titrimetric methods with catalytic end-point indication (catalytic titration) for the determination of inorganic and organic compounds have increased. Since 1960, about 200 papers on catalytic titrimetric procedures have been published for the determination of catalysts and other species by photometric, potentiometric, biamperometric and thermometric techniques.

The methodology involves two consecutive reactions, i.e. titration and indicator reactions. The titration reaction is expressed as Equation (21):

$$L + M \longrightarrow ML \qquad (21)$$

where L, M and ML are the titrated component (inhibitor), titrant (catalyst) and titration product (catalytically inactive), respectively.

As described in section 2, the indicator reaction is expressed as Equation (2):

$$S + R \longrightarrow P + Q \qquad (2)$$

A small excess of the titrant M added after the equivalence point catalyzes the indicator reaction and this

catalyzed reaction is used to detect the end-point of the titration. As previously noted, rapid regeneration of M by Equation (4) results in the catalytic formation of the product P, and thus trace amounts of M lead to marked color changes in the end-point of the solution titrated. It is thus possible to determine trace amounts of the catalyst M when a small excess of the titrant M is added to the known amount of the titrated component such as EDTA.

Some examples of the titrimetric methods for the determination of metals (catalyst) or inhibitors are compiled in Table 2.[67,69–81] Other interesting approaches are briefly reviewed below.

The oxidation of 1,4-dihydroxyphthalimide dioxime (DHPO) by iodate is catalyzed by nickel(II); the oxidation product has an absorption maximum at 510 nm. The indicator reaction is used for the determination of inhibitory substances such as EDTA and CDTA, and also for the indirect titration of nickel(II), mercury(II) and iron(III).[82] Amounts of EDTA and CDTA in the range 700–6000 μg are determined.

A semiautomatic spectrophotometric method of end-point indication for indirect catalytic titrations of alkaline earth ions has been developed.[83] The manganese(II)-catalyzed autoxidation of 1,4-dihydroxyphthalimide dithiosemicarbazone is used as an indicator reaction. Calcium and magnesium (10–150 μg), strontium (20–250 μg), and barium (20–450 μg) can be determined by adding a known excess of EDTA to the sample solution and back-titrating the unconsumed inhibitor agent with standard manganese(II) solution. This method is applied to the determination of the total concentration of calcium and magnesium (total hardness) in natural waters and milk.

Gaal et al.[84] investigated the applicability of the conductometric detection to catalytic end-point indication of neutralization titrations. Conductometric and high-frequency conductometric methods are used for the titration of sodium acetate, as well as some organic bases (antipyrine, aminopyrine, caffeine, etc.) with perchloric acid by using the acetic anhydride–methanol or acetic anhydride–formic acid system which is catalyzed by excess titrant (perchloric acid).

A simple catalytic end-point indication has been developed for total concentrations of heavy metal ions which form more stable EDTA complexes than manganese(II).[85] The method is based on the substitution reaction of manganese(II)–EDTA and heavy metal ions to produce manganese(II). The end-point is determined by the manganese(II)-catalyzed oxidation of Acid Blue 45 dye (1,5-dihydroxy-4,8-diaminoanthraquinone-2,6-disulfonate) with hydrogen peroxide as a result of decoloration. The method is applicable to the determination of heavy metal ions in river and groundwater samples.

A semiautomatic spotting method is used for end-point detection.[86] In this method metal ion catalysts in the range 3–70 $\mu g\,mL^{-1}$ are titrated with EDTA. The necessary assembly consists of a titration vessel, mixing chamber, automatic syringe burette, PTFE (polytetrafluoroethylene)-coated belt (a moving band) and connection tubes. In an example copper(II) is visually determined by using a copper-catalyzed hydroquinone/hydrogen peroxide reaction in the presence of bpy as activator. The titration vessel is completely filled with a sample solution of copper(II) (avoiding gas bubbles). The reagent solutions for the indicator reaction are delivered to the mixing chamber from two automatic syringe burettes at a constant speed. After a few drops of the reagent, solutions leave the mixing chamber for the belt (which is not moving yet), the EDTA titrant is propelled to the titration vessel at a constant speed by the syringe burette. Simultaneously, the PTFE-coated belt starts to move at a constant speed. Because the titration vessel is completely filled with the sample solution, excess solution containing EDTA and copper(II) is pushed out of the titration vessel into the mixing chamber where the catalyzed reaction occurs. Before the end-point, the drops on the moving belt are red–brown caused by formation of products of the copper-catalyzed reaction; after the end-point, the drops are colorless. The first drop which shows a color change corresponds to the end-point. Calibration graphs are prepared by plotting titration time versus copper concentration.

The catalytic titration of aminopolycarboxylic acids (EDTA, GEDTA, CDTA and DTPA) using manganese(II) as a titrant and the manganese-catalyzed periodate–diethylaniline reaction, which acts as an indicator reaction, has been developed to demonstrate the usefulness of flow injection pseudotitration in catalytic titrimetry.[87] The titrant and each reagent for the indicator reaction are mixed in a 100-cm mixing coil and the mixing chamber, and then allowed to react in a 3-m reaction coil. When an aminopolycarboxylic acid sample solution (200 μL) is injected into the reacting flowstream, the catalysis is inhibited by the formation of the manganese–aminopolycarboxylic acid complex, and the uncatalyzed reaction is monitored, resulting in the transmittance being increased from 3% to 75%. The FIA peak width depends on the aminopolycarboxylic acid concentration in the range 5×10^{-6}–1×10^{-2} M.

Raya-Saro and Perez-Bendito[73,74] reported a method for the simultaneous catalytic titration of binary mixtures of mercury(II) with copper(II) or cadmium at the micromolar level by using the oxidation of DBPT by hydrogen peroxide as an indicator reaction. Copper(II) and mercury(II) ions act as catalyst and inhibitor for the indicator reaction, respectively. The combination of the

Table 2 Titrations with catalytic end-point indication

Indicator reaction	Analyte	Titrant	Titrand	Detection technique	Dynamic range	Application	Ref.
Ascorbic acid + O_2	Cyanide	Cu(II)	Cyanide	Photometry	10^{-7} M level		67

[a] By the indirect back-titration method.

[b] Binary mixture.

[c] Two sample aliquots are necessary. Triethanolamine or fluoride was used as a masking agent for iron(III) in the determination of copper, nickel or manganese only.

[d] Copper(II) and mercury(II) act as a catalyst and an inhibitor, respectively. Cysteine has a counter-inhibitory effect on mercury. Cystine is reduced to cysteine by hydroxylamine. Two catalytic titration runs, in the absence and presence of hydroxylamine, are needed for each sample.

[e] In this method free mineral acids have been simultaneously determined with turbidimetric end-point indication.

[f] Amounts of the active ingredients (e.g. hyoscine butyl bromide, pyridostigmine bromide and neostigmine bromide).

catalytic effect of copper(II) and the inhibitory effect of mercury(II), along with the blocking of the catalytic cycle by EDTA are used as the basis for titrimetric methods for individual and simultaneous titrations of mercury and copper or cadmium, with catalytic end-point detection.

A gaseous catalyst (hydrogen sulfide) is also used for the end-point indication in titrimetric analysis of metal ions with the hydrogen sulfide-catalyzed iodine–azide reaction as an indicator reaction.[88] Sodium sulfide can be used as a standard solution for the determination of metal ions such as antimony, nickel, iron, mercury plus cadmium, lead plus copper and silver plus copper (precipitation) and permanganate (redox reaction) both in acidic solution. Once the metal ions are fully precipitated or reduced by sodium sulfide, hydrogen sulfide is liberated and transferred by a stream of nitrogen gas into the separate indicator vessel containing the solution of sodium azide, iodine and starch. Thus the color of the solution disappears at the end-point.

7 KINETIC–CATALYTIC METHODS FOR TRACE ELEMENTS

A large number of publications devoted to kinetic–catalytic determination of trace elements that obtain higher sensitivity and better selectivity have been reported, with a marked trend toward its application to environmental, clinical, pharmaceutical and agricultural samples. The determination of a single species in a mixture is the most popular area of the kinetic–catalytic method. Relatively few methods are reported for the simultaneous determination of two components. This section describes the kinetic–catalytic determination for trace elements using redox and ligand substitution reactions.

7.1 Catalytic Methods Using Redox Reactions

Inorganic and organic redox reactions are extensively used for kinetic–catalytic methods. These methods focus on the determination of transition metal ions such as copper, cobalt, manganese, iron and vanadium. Tables 3–9[53–56,58,61,62,89–263] show selected methods

Table 3 Kinetic–catalytic methods for determination of copper

Tiron, 1,2-dihydroxybenzene-3,5-disulfonic acid; DPDA, *N*,*N*′-diethyl-*p*-phenylenediamine; AHHNS, 1-amino-8-hydroxy-7-(*p*-hydrophenylazo)-3,6-naphthalenedisulfonic acid; DHBA, 3,4-dihydroxybenzoic acid, Br-PAPS, 2-(5-bromo-2-pyridylazo)-5-(*N*-propyl-*N*-sulfopropylamino)phenolate; THCPF, 2,6,7-trihydroxy-9-(4′-chlorophenyl)-3-fluorone; DMSO, dimethyl sulfoxide; CTAB, cetyltrimethylammonium bromide; HQ, 8-hydroxyquinoline; 8-quinolinol; IC, ion chromatography. Other abbreviations as in Table 3.

based on catalyzed-redox reactions. Of these, spectrophotometry occupies a predominant position because of the wide use of colored organic compounds.

When the reactants of the indicator reaction have high absorptivity for monitoring the reaction rate, it is preferable to combine the catalyzed reaction with a second coupling reaction yielding a colored product. An oxidative coupling reaction of *p*-anisidine with DMA in the presence of hydrogen peroxide is used as an indicator reaction for the kinetic–catalytic determination of Fe(III)[53] and Cu(II).[91] That is, *p*-anisidine reacts with DMA to form Variamine Blue B leuco base analog, MDP. MDP is oxidized to a blue compound *N*-(*p*-methoxyphenyl)-*N*′,*N*′-dimethyl-1,4-benzoquinonediiminium ion (MDB) by trace amounts of Fe(III) and Cu(II) in the presence of H_2O_2. By using the reactants separately, the blank values can be kept low, decomposition and oxidation of the product during storage being avoided. Similarly, an oxidative coupling reaction of MBTH with DMA in the presence of H_2O_2 is used as an indicator reaction for the catalytic determination of Cu(II),[55,95,96] Cr(III),[58] Mn(II),[54,154] Co(II)[124] and Fe(II, III)[149] at nanograms per milliliter levels, Equations (22) and (23)

$$\text{MBTH} + \text{DMA} + \text{M}^{(n+1)+} \longrightarrow \text{indamine dye} + \text{M}^{n+} \quad (\lambda_{max} = 590\,\text{nm}) \qquad (22)$$

$$\text{M}^{n+} \xrightarrow{\text{H}_2\text{O}_2} \text{M}^{(n+1)+} \qquad (23)$$

In these reaction systems, the use of activators allows an increase in the sensitivity. Among them, catalytic effects of Cr(III) and Co(II) in the presence of activators are worthy of remark. EDTA acts as an activator for Cr(III), because the Cr(III)–EDTA complex catalyzes the decomposition of H_2O_2. On the other hand, Cr(VI) has hardly any catalytic action in this reaction because of the formation of a peroxochromium(VI) complex and slow production of Cr(III) from this complex.[58] In the Co(II)-catalyzed reaction system, the extremely high activating effect is obtained by using two activators,

i.e. Tiron and hydrogen carbonate.[124] In addition, the sensitivity of the method with FIA is improved in the presence of SDS at concentrations above its CMC.[124] The peak height in the presence of SDS is about eight times as high as that without it. By using modified Trinder's reagents instead of DMA as a coupling agent for MBTH, the catalytic effect of Cu(II) is examined.[97] It is found that DAOS is the most sensitive reagent for Cu(II) and pyridine is selected as the most effective activator for Cu(II) in this system. A Cu(II) concentration as low as 10^{-11} M can easily be determined by using the fixed time procedure, and the method has been successfully applied to the copper determination in real samples.

The oxidative coupling of PPDA with DMA or PDA in the presence of an oxidizing agent is utilized for the catalytic determination of Cu(II),[92,93] Fe(II, III)[133,134] and V(V)[174] with manual and FIA procedures. For the determination of Cu(II) and Fe(II, III), hydrogen peroxide is used as an oxidant. Activators for Cu(II) and Fe(II, III) are ammonia and acetate, respectively. In the FIA determination, Tween 80 acting as a nonionic surfactant improves the sensitivity and sampling frequency. Concentrations of Cu(II) and Fe(II, III) at 10^{-9}–10^{-8} M levels can be determined from the increase in the absorbance of the product at a fixed time. For the V(V) determination, bromate and tartrate are used as an oxidant and an activator, respectively.

The oxidative coupling of AA with DMA in the presence of bromate is used for the catalytic determination of V(IV, V) in the manual[178,179] and FIA[57] mode. In this reaction system, SSA and Tiron act as activators. The combination of this method and solvent extraction of vanadium with *N*-cinnamoyl-*N*-(2,3-xylyl)hydroxylamine (CXA) allows the differential determination of V(IV) and V(V) in natural waters.[179]

Fluorimetry is an effective tool for monitoring the rate of reaction. However, these are fewer catalytic fluorimetric methods than spectrophotometric ones. Valcarcel et al.[153] have reported catalytic methods based on fluorimetric reactions; the H_2O_2 oxidation of PPH is adopted for the determination of Mn(II). Applying the tangent, fixed time and fixed intensity procedures, Mn(II) concentration in the range 0.05–8 ng mL^{-1} can be determined.

Several kinetic–catalytic methods for the determination of catalysts have been developed by using thermometric methods. Although the sensitivity of the methods is lower than that of spectrophotometric and fluorimetric detections, thermometric monitoring has other advantages; the presence of colored compounds and/or precipitates in the samples does not affect the thermometric detection. On the basis of Co(II)-catalyzed oxidation of DHBA by H_2O_2, a thermometric determination of Co(II) is developed with the aid of a personal

computer system.[121] The calibration graph is linear in the range 1–16 ng mL^{-1} Co(II) and the method is applied to the pharmaceutical sample.

Thermal lens spectrometry (TLS) is 100–1000 times more sensitive than conventional spectrophotometry and is used for monitoring the rate of the bromate oxidation of aniline catalyzed by V(V) in the presence of 8-quinolinol or pyrocatechol as an activator.[189] The DL of the TLS method is 100 times lower than that of the spectrophotometric method.

The oxidation of CL reagent with a suitable oxidant has been applied to the kinetic–catalytic determination of transition metal ions by many workers. CL methods have some advantages in simplicity of instrumentation, low limits of detection and a wide dynamic range. Further, the use of a CL reaction with FIA techniques allows rapid and reproducible determination. However, the application of the method to real samples is difficult because of its lack of specificity. Several separation procedures such as ion exchange, solvent extraction and a membrane phase separator are used prior to the determination of a catalyst as well as the use of a masking agent. A luminol CL reaction is utilized for the determination of transition metal ions by FIA with separation processes.[128,151] The CL oxidation of gallic acid with H_2O_2 is adopted for the flow-injection determination of Co(II) with an in-line column of immobilized 8-quinolinol.[126] The method enables the determination of picomolar levels of Co(II) in seawater. The oxidation of brilliant sulfoflavine with H_2O_2 is adapted for the CL–FIA determination of Fe(II).[150] A cation column is used to preconcentrate the iron in seawater. The DL of the method is 0.45×10^{-9} M when 4.4 mL of sample is passed through the column.

There are several methods for the determination of anions containing nonmetals, although most catalytic determinations are intended to determine various metals.[26,27] Iodide ion can be determined by its catalytic effect on the redox reaction between As(III) and Ce(IV)

NA, 1-naphthylamine; SSA, 5-sulfosalicylic acid. Other abbreviations as in Tables 3–6.

in sulfuric acid solution.[3,4] This reaction proceeds very slowly, but traces of iodide increase the rate of the reaction. The rate of the reaction is proportional to the iodide concentration: the time required for the yellow color of Ce(IV) to disappear is inversely proportional to the amounts of iodide present in solution. The determination of iodide based on this reaction has been used extensively by many workers.[3,4,264–268] This reaction is also catalyzed by Os,[64,269–272] Ru[64,273] and Cr[272] in the same way as iodide.

The catalytic effect of nitrite on the bromate oxidation of phenosafranine is used for the fluorimetric determination in the range 0.9–1.38 ng mL^{-1} nitrite using the manual procedure.[254] This reaction system is applied to the FIA in the stopped-flow mode; the dynamic range of the FIA method is 46–460 ng mL^{-1}. The oxidative coupling of PPDA with DMA in the presence of bromate is also utilized for the nitrite determination; nitrite at the amounts of 2–100 ng mL^{-1} in river water can be determined using the FIA mode.[261]

Many differential kinetic methods based on uncatalyzed reactions have been proposed for the analysis of mixtures involving closely related compounds without prior separation. By using catalyzed reactions, a few methods for the simultaneous determination of two catalysts are reported; they are listed in Table 10.[274–286] A method for the differential determination of Mo(VI) and W(VI) based on their different catalytic effects on the oxidation of chloropromazine by H_2O_2 has been proposed.[284] The initial rates at two different H_2O_2 concentrations and the corresponding rate equations are obtained; mixtures of Mo(VI) and W(VI) in the 10^{-7} M range can be determined. The method is applied to the

determination of these ions in hot spring water. The simultaneous determination of these ions in a single kinetic run is of interest.

Principal component regression (PCR) has been employed in data processing of multicomponent analysis. Zhu et al.[285] have developed a simultaneous determination of Os(VIII) and Ru(IV) based on their catalytic action on the reaction between As(III) and Ce(IV), applying PCR to calculate the concentration of each catalyst.

7.2 Catalytic Methods Using Ligand Substitution and Complex Formation Reactions

The catalytic determinations of some metal ions and inorganic anions using ligand substitution and complex formation reactions are shown in Table 11.[50,287–303] The ligand substitution reaction of the Hg(II) complex of CAC with CDTA (Equation 24) is used for the catalytic determination of trace amounts of ammonia.[295]

$$Hg^{II}\text{–CAC} + \text{CDTA} \longrightarrow Hg^{II}\text{–CDTA} + \text{CAC} \quad (24)$$

The rate equation for Equation (24) in the presence of ammonia is expressed as Equations (25) and (26):

$$-\frac{d[Hg^{II}\text{–CAC}]}{dt} = k_0[Hg^{II}\text{–CAC}] \quad (25)$$

and

$$k_0 = \frac{k_1' + k_2'[H^+] + k_3'[H^+][NH_3]}{[\text{CAC}][\text{CDTA}]} \quad (26)$$

where k_1', k_2' and k_3' refer to conditional rate constants. This reaction path, corresponding to the third term on the right-hand side of Equation (26), is expressed as Equations (27) and (28)

$$Hg\text{–CAC} + NH_3 \longrightarrow HgNH_3 + \text{CAC} \quad (27)$$

$$HgNH_3 + \text{CDTA} \longrightarrow Hg\text{–CDTA} + NH_3 \quad (28)$$

This provides the basis of the determination of ammonia. From the absorbance of Hg^{II}–CAC complex at a fixed time, the concentration of ammonia at micromolar levels can be determined. Interferences from cationic and anionic ions are avoided by distillation of ammonia at room temperature.

DPDKPH, dipyridyldiketone phenylhydrazone; SAT, salicylaldehyde thiosemicarbazone; DAP, 2,4-diaminophenol; PCV, pyrocatechol violet. Other abbreviations as in Tables 3–9.

The ligand substitution of Hg^{II}–4-(2-pyridylazo)resorcinol (H_2PAR) complex of CDTA is catalytically accelerated by a trace amount of iodide, Equation (29)

$$Hg(PAR)_2^{2-} + HCDTA^{3-} + H^+ \longrightarrow Hg(CDTA)^{2-} + 2HPAR^- \quad (29)$$

According to detailed studies of the kinetics and mechanism of the reaction,[300] $Hg(PAR)_2^{2-}$ dissociates to Hg(PAR) which then reacts with iodide to form a mixed ligand complex, $Hg(PAR)I^-$, which is more reactive with CDTA than Hg(PAR). The rate-determining step is the dissociation of the PAR molecule from Hg(PAR), $Hg(PAR)OH^-$ and $Hg(PAR)I^-$. Iodide and hydroxide ions enhance the rate of the dissociation of PAR molecule by their electron donation. The rate equation of Equation (29) is given as follows, Equations (30) and (31):

$$-\frac{d[Hg(PAR)_2^{2-}]}{dt} = k_0[Hg(PAR)_2^{2-}][HCDTA^{3-}] \quad (30)$$

and

$$k_0 = (k_1'[H^+] + k_2' + k_3'[H^+][I^-])[HPAR^-]^{-1} \quad (31)$$

From Equation (31), the conditional constant k_0 is a linear function of the iodide concentration when PAR is present in large excess and the pH is constant. By measuring the absorbance change at 500 nm, up to 2×10^{-7} M iodide can be determined. The method is applied to rainwater after separation of interfering ions using a cation exchanger. From the kinetic investigation of the ligand substitution reaction between the Hg^{II}–PAR complex and CDTA together with the catalytic effect of some inorganic ligands on this reaction, the difference

PDTS, 3-(2-pyridyl)-5,6-diphenyl-1,2,4-triazine-*p*,*p*′-disulfonic acid; INH, isonicotinoyl hydrazine; $DDTC_{org}$, diethyldithiocarbamic acid in organic solvent; TPPS, 5,10,15,20-tetra(*p*-sulfonatophenyl)porphine; TARPO, 4-(2′-thiazolylazo)resacetophenone oxime; CAC, 3,3′-bis[*N*,*N*-bis(carboxymethyl)aminomethyl]*o*-cresolphthalein; XO, xylenol orange; MTB, methylthymol blue; PAR, 4-(2-pyridylazo)resorcinol; CTAC, cetyltrimethylammonium chloride; SEFIA, solvent extraction flow injection analysis. Other abbreviations as in Tables 3–10.

in reactivity between sulfite or thiosulfate and sulfate is established; the differential kinetic determinations of sulfite and thiosulfate are designed from the observations. Sulfite up to 1.5×10^{-6} M and thiosulfate up to 7×10^{-7} M can be determined in the presence of 10^4 and 2.5×10^4-fold molar amounts of sulfate under the optimized conditions.[302]

Catalytic determinations of Ag(I) and Hg(I) are proposed using ligand substitutions of cyano and aminocyano complexes of iron with chromogenic organic ligands such as phen,[293] PDTS[287] and INH.[288]

A metal exchange reaction between ethylenediaminetetraacetatomercury(II) (Hg^{II}–EDTA) in aqueous phase and bis(diethyldithiocarbamato)copper(II) (Cu^{II}–DDTC) in the organic phase is catalyzed by trace amounts of Ag(I), Equation (32).[289]

$$Cu^{II}\text{–}DDTC_{org} + Hg^{II}\text{–}EDTA \longrightarrow Hg^{II}\text{–}DDTC_{org} + Cu^{II}\text{–}EDTA \quad (32)$$

where org denotes the organic phase. By measuring the decrease in the absorbance of the Cu^{II}–DDTC complex, Ag(I) at 10^{-7} M levels can be determined with the flow-injection mode.

Complex formations of metal ions with porphyrine derivatives are attractive reactions for kinetic-based methods. The rate of the incorporation of Mn(II) into TPPS is very slow, so that little spectral change is observed even 60 min after initiation of the reaction at 25 °C.[290] In the presence of Hg(II) or Cd(II), a rapid spectral

change occurs. Mercury(II) also accelerates the complex formation of H_2TPPS with Ni(II), Co(II) and Cu(II). In the metalloporphyrin formation reaction catalyzed by metal ions, the ionic radius (r) of the metal ion acting as a catalyst is an important factor. Large metal ions such as Cd^{2+} ($r = 95$ pm), Cu^{+} ($r = 96$ pm), Pb^{2+} ($r = 73$ pm) and Hg^{2+} ($r = 114$ pm) give rise to an appreciable catalytic effect, while medium-sized ions like Cu^{2+} ($r = 73$ pm) and Zn^{2+} ($r = 75$ pm) exert hardly any catalytic effect.

In the formation of Mn^{II} (TPPS) catalyzed by Cd(II), the following reaction paths are proposed from the mechanical study,[290] Equations (33–35):

$$\mathrm{Mn(II)} + \mathrm{TPPS} \longrightarrow \mathrm{Mn^{II}TPPS\ (slow)} \quad (33)$$

$$\mathrm{Cd(II)} + \mathrm{TPPS} \rightleftharpoons \mathrm{Cd^{II}TPPS} \quad (34)$$

$$\mathrm{Cd^{II}TPPS} + \mathrm{Mn(II)} \longrightarrow \mathrm{Mn^{II}TPPS} + \mathrm{Cd(II)\ (fast)} \quad (35)$$

Cadmium(II), having a large ionic radius, will distort the configuration of the porphine core which favors the attack of porphine nucleus by Mn(II) from behind (Equation 34). After the incorporation of Mn(II) (Equation 35), Cd(II) is liberated and takes part in the formation of Mn^{II}TPPS. On the basis of this consideration, the catalytic determination of Cd(II) has been developed: as little as 10^{-7} M Cd(II) can be determined from the decrease in absorbance of TPPS using a fixed time procedure.[290] Since lead(II) interferes with the determination, it needs to separated from Cd(II) by coprecipitation with manganese(IV) oxide.

Mercury(II) and Pb(II) also act as catalysts for the complex formation of TPPS with Mn(II) (Equation 33) in the same way as Cd(II). The catalytic methods for the determination of Hg(II) and Pb(II) are constructed using this complex formation. After separation of metallic mercury by distillation, concentrations of Hg(II) as low as 10^{-8} M can be determined.[291] To determine Pb(II), interferences from Hg(II) and Cd(II) should be avoided by the addition of hydroxylamine and cyanide.[294] Lead(II) concentrations at 10^{-7} M levels can be determined.

Although the rate of complex formation of Cr(III) with a ligand such as chromazurol S[298] and EDTA[299] is slow, this reaction is catalytically accelerated in the presence of carbonate and/or bicarbonate. By using these systems, the anions can be determined by spectrophotometry. The catalytic effect of fluoride[296,297] and sulfate[303] on the complex formation of Zr(IV) with XO is utilized for the determination of these anions.

The vast development in kinetic methods is a result of improvements in the sensitivity and selectivity brought about by the use of catalyzed reactions. These have facilitated the determination of microconstituents in various types of samples by straightforward and inexpensive instrumentation.

The number of papers devoted to kinetic photometric determination continues to be high, with a marked trend towards the application of the methods development to real sample analyses. Methods focus on the determination of transition metal ions like copper, manganese and iron, and are based on their catalytic effects on redox reactions. Relatively few methods for the determination of nonmetals and organic compounds are reported.

ACKNOWLEDGMENTS

This article was inspired by Professor A. Meyers and the editors of *Encyclopedia of Analytical Chemistry*. During the writing of this manuscript, the constant encouragement and valuable advice of the editors have been given. We also wish to thank Managing Editor, Dr Adam Holyoake, for his encouragement and constructive comments on this manuscript.

Rhodamine B	9-(2-Carboxyphenyl)-3,6-bis-(diethylamino)xanthylium Chloride
Rhodamine 6G	Ethyl-2-(6-ethylamino-3-ethylimino-3*H*-xanthen-9-yl)-benzoate Hydrochloride
Safranine	3,7-Diamino-2,8-dimethyl-5-phenylphenazonium Chloride
Sulfanilic Acid	4-Aminobenzenesulfonic Acid
Tetrabase	4,4′-Bis(dimethylamino)-diphenylmethane
Thionine	3,7-Diaminophenothiazine-5-ium Chloride
Tiron	Disodium Salt of 1,2-Dihydroxybenzene-3,5-disulfonic Acid
Thymol blue	Thymolsulfonephthalein; 4,4′-(3*H*-2,1-benzoxathiol-3-ylidene)bis[5-methyl-2-(1-methylene)phenol] *S*,*S*-Dioxide
Toluidine Blue	2-Methyl-3-amino-7-dimethylaminophenazothionium Chloride
Variamine Blue B leuco base analog	*N*-(*p*-Methoxyphenyl)-*N*′,*N*′-dimethyl-*p*-phenylenediamine
Xylenol Orange	3,3′-Bis[*N*,*N*-di(carboxymethyl)-aminomethyl]-*o*-cresolsulfonenaphthalein
Zephiramine	Benzyldimethyltetradecylammonium Chloride

Methods of data treatment in kinetics are reviewed from a practical viewpoint. The equations to describe the kinetics of chemical reactions and the methodology to obtain the models are presented. Moreover, the integration methods that are needed for the simulation of complex reactions are explained, from the simple first-order reaction to the complex general mechanism.

However, it is essential to know the main sources of error in data treatment in order to reduce their effects on the results. Stress is put on the analysis of the errors due to the simplification of complex models. The different factors that influence the kinetics of the reaction are reviewed. How to take advantage of the kinetic information contained in the experimental data with an analytical aim is described. Finally, the propagation of errors in the analytical results is studied, reviewing both the simple univariate methods, used to determine one species, as well as the complex multivariate methods devoted to the determination of multicomponent mixtures.

1 INTRODUCTION

Modern kinetic methods have benefited from the development of sophisticated data treatment techniques, the increasing availability of inexpensive computers, and the tremendous advances in instrumentation that is able to provide reliable data. For many years, most kinetic-based methods have been performed under pseudo-first-order conditions, which use simpler mathematical procedures. This approach is simplification of the reaction mechanism, carried out with an excess of reagent concentration, and aims to produce a reduction in the reaction order. However, the effective exploitation of the analytical potential of kinetics determinations requires the processing, without simplifications, of the actual reaction mechanism. Several approaches, such as the fractional time method, can be applied to elucidate the rate equations from which the concentrations of the species involved in the reaction can be calculated as a function of time. The differential nature of rate equations is a particular characteristic of kinetic methods, and it makes necessary the use of numerical methods to integrate accurately the rate equations.

Most kinetic methods are strongly dependent on factors affecting the reaction rate, such as temperature, ionic strength, or pH. Thus, reproducibility in the experimental conditions in each determination is critical, because variations can lead to important errors. Therefore, to assure the quality of the results, an effective data treatment in kinetics determinations requires an error analysis that quantifies the uncertainty inherent to the kinetic measurement. The study of error sources and propagation provides a means to obtain the optimal experimental design, thus improving the final results. An additional control of errors can be obtained by using multivariate methods, aimed at determining simultaneously several species, together with multidimensional data. The Kalman filter (KF) algorithm has been widely used, giving excellent results and providing error compensation capabilities, so that a large variation in rate constants is tolerated with little error.

2 DATA TREATMENT IN CHEMICAL KINETICS

2.1 The Scope of Chemical Kinetics

Chemical kinetics is concerned with the measurement and interpretation of the reaction rates, and, traditionally, it has been divided into molecular kinetics, dealing with the description of how reactions proceed at a molecular level, and formal kinetics, devoted to the empirical study of the reacting systems. More precisely, the objective of formal

kinetics is to induce from experience a chemical model, *the reaction mechanism*, explaining how the reaction takes place, and to develop a suitable mathematical model, *the rate law*, explaining the concentration variation with time of all chemical species of the reacting system.

Analytical chemists are mainly interested in the methodology of formal kinetics, since the mechanism of a reaction and the rate law should be known prior to their usage as an analytical tool.

2.2 The Reaction Rate

Let us suppose a reaction taking place according to the stoichiometric equation shown in Equation (1):

$$\nu_A A + \nu_R R \longrightarrow \nu_P P \tag{1}$$

where A and R are reactants and P the product. The rate of such a process in a closed reactor is defined in Equation (2) as the variation with time in the number of moles generated by the chemical reaction:

$$v = \frac{1}{\nu_i}\frac{1}{V}\frac{dn_i}{dt} \tag{2}$$

where n_i is the number of moles of species i, V the reactor volume, and ν_i the stoichiometric coefficient, which is taken as positive for products and negative for reactants to ensure the positive sign of the reaction rate. The introduction of ν_i and V makes the above definition independent of the chemical species used to follow the reaction, and on the reacting system size, respectively. Equation (2) turns into the usual definition of reaction rate, when volume remains constant during the reaction as shown in Equation (3):

$$v = \frac{1}{\nu_i}\frac{d}{dt}\frac{n_i}{V} = \frac{1}{\nu_i}\frac{dc_i}{dt} \tag{3}$$

where c_i is the concentration of the ith reactant. Strictly speaking, the volume remains constant only for gas reactions taking place in a closed rigid reactor. For reactions in solution, Equation (3) does not stand exactly, since the volume of the reaction mixture depends on composition and, consequently, on time. Nevertheless, the volume can be considered as a constant for dilute solutions reacting isothermally. On the other hand, most of the physical properties used to follow the kinetics of a reaction depend linearly on the molar concentration of species.

2.3 The Rate Law

Reactions can be divided into elementary and complex according to their kinetic mechanism. An *elementary* reaction takes place in a single step through a unique transition state. The transition state is the complex formed by the reactants to achieve the products. Figure 1 illustrates the energy changes during this process. There is an energy barrier to the reaction because reactants must take energy to form the transition state. The difference in energy between the transition state and the reactants is called the activation energy. On the other hand, complex reactions consist of two or more elementary steps.

Figure 1 Potential energy–reaction coordinate diagram for a hypothetical elementary reaction. (The final energy is not always lower than the initial energy.)

The rate law relates the reaction rate with system composition (at constant temperature and pressure), and its mathematical form can be established from stoichiometry only for elementary reactions. According to the Law of Mass Action, the general rate equation of an elementary reaction is shown by Equation (4):

$$v = \frac{1}{\nu_i}\frac{dc_i}{dt} = k\prod_{i=1}^{M} c_i^{\nu_i} \tag{4}$$

where k is the rate constant (or specific rate) of the reaction, M the number of reactants, and ν_i is taken as positive. The rate constant depends on pressure, on temperature, and, for reactions taking place between ions, on electrolyte concentration.

For complex reactions, the comprehensive experimental work carried out in chemical kinetics from the beginning of the 20th century allows the rate laws to be classified into simple and complicated.

A simple rate law can be expressed, in a similar manner to elementary reactions, by Equation (5):

$$v = \frac{1}{\nu_i}\frac{dc_i}{dt} = k\prod_{i=1}^{M} c_i^{\gamma_i} \tag{5}$$

where γ_i is the reaction order with regard to the ith reactant. The reaction orders are empirical parameters induced from experience and whose values coincide with the stoichiometric coefficients only for elementary reactions. The sum of the reaction orders is the *overall order* of the reaction. For reactions with simple rate laws, the change of concentrations with time can be described by a single extent of reaction. The study of the kinetics of a single reaction is reduced to calculating k and the reaction orders.

2.4 The Mechanism of Reaction and the Rate Law

As previously stated, elementary reactions take place though a unique transition state and their rate law can be easily established. However, most chemical reactions are not elementary, and must be described by a *reaction mechanism*, which shows how the reaction takes place and must include all the contributing elementary reactions and the intermediate species formed. Thus, the reaction mechanism is the *chemical model* associated with a reaction while the rate law is the associated *mathematical model*. Once the mechanism is postulated, the mathematical model, which consists of an ordinary differential equation (o.d.e.) system, can be easily derived. Each differential equation of the system is the global derivative of the species concentration with regard to time, which is obtained by summation over the reaction rates of the elementary reactions where the species takes part, multiplied by its stoichiometric coefficient.

Let us consider, as an example, a simple enzyme-catalyzed reaction with the stoichiometry shown in Equation (6):

$$\mathrm{E} + \mathrm{S} \longrightarrow \mathrm{E} + \mathrm{P} \tag{6}$$

where E is the enzyme and S the substrate. Equation (7) is the simplest kinetic mechanism that can account for this reaction with three elementary steps:

$$\mathrm{E} + \mathrm{S} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{ES} \xrightarrow{k_2} \mathrm{E} + \mathrm{P} \tag{7}$$

where ES is an enzyme–substrate complex. From this mechanism, it is possible to build the differential equation system shown in Equations (8–11):

$$\frac{\mathrm{d[E]}}{\mathrm{d}t} = -k_1[\mathrm{E}][\mathrm{S}] + k_{-1}[\mathrm{ES}] + k_2[\mathrm{ES}] \tag{8}$$

$$\frac{\mathrm{d[S]}}{\mathrm{d}t} = -k_1[\mathrm{E}][\mathrm{S}] + k_{-1}[\mathrm{ES}] \tag{9}$$

$$\frac{\mathrm{d[ES]}}{\mathrm{d}t} = k_1[\mathrm{E}][\mathrm{S}] - k_{-1}[\mathrm{ES}] - k_2[\mathrm{ES}] \tag{10}$$

$$\frac{\mathrm{d[P]}}{\mathrm{d}t} = k_2[\mathrm{ES}] \tag{11}$$

The concentration of species is obtained by integration of the o.d.e., but most o.d.e. systems do not have analytical solutions and must be integrated numerically. However, taking into account the relative rate at which the elementary reactions occur, sometimes the mathematical model can be simplified. The most popular simplifications arise from the use of the *steady-state* and the *pre-equilibrium state* hypotheses, together with the assumption of the existence of a *rate-limiting step*.

2.4.1 Steady-state Hypothesis

Usually, reactions proceed through highly reactive species such as free radicals, ions, or reaction sites on the surface of a catalyst or enzymes. Owing to the intrinsic instability of these intermediates, their concentration will tend to remain low and constant compared to those of reactants and products. These facts are the basis of the steady-state hypothesis, in which the accumulation rate of a highly reactive intermediate is considered null and its associated differential equations equal to zero. Thus, its o.d.e. becomes an algebraic equation that allows the steady concentration of the intermediate to be related to the concentration of reactants and products. Since the concentration of the highly reactive intermediate remains low compared to that of reactants and products, it can be neglected in the concentration balances.

Steady-state hypothesis is often used to simplify enzymatic catalysis data treatment because once the steady state is accomplished for the enzyme–substrate complex, ES, the differential Equation (10) turns into the algebraic equation shown in Equation (12):

$$k_1[\mathrm{E}][\mathrm{S}] - k_{-1}[\mathrm{ES}] - k_2[\mathrm{ES}] = 0 \tag{12}$$

This equation allows us to express the ES concentration as a function of the reactant concentrations:

$$[\mathrm{ES}] = \frac{k_1}{k_{-1} + k_2}[\mathrm{E}][\mathrm{S}] \tag{13}$$

The overall reaction rate is determined by the product formation rate and after substituting Equation (13) into Equation (11), it yields Equation (14):

$$v = \frac{\mathrm{d[P]}}{\mathrm{d}t} = k_2[\mathrm{ES}] = \frac{k_2 k_1}{k_{-1} + k_2}[\mathrm{E}][\mathrm{S}] \tag{14}$$

This solution will be valid as long as the steady-state approximation remains valid. At the beginning of the reaction this hypothesis cannot be applied because the concentration of the intermediate is building up from its initial value of zero to the steady-state value.

2.4.2 Rate-limiting and Pre-equilibrium Steps

The reaction rate of the elementary steps of a mechanism can be very different. When there is a step much slower

than the others, it controls the rate of the overall reaction and the formation rate of final products equals the rate of this step, that is called the *rate-limiting step*. On the other hand, some mechanisms exhibit a rate-limiting step preceded by a fast reversible step. Then, it can be considered that the fast reversible step reaches the equilibrium being unperturbed by the following much slower step. Now the concentration of the intermediate can be obtained by solving the equilibrium equation. A system of this type is said to possess a fast *pre-equilibrium step*. Proton transfers constitute a very important class of fast pre-equilibrium step as in acid-catalyzed reactions. Pre-equilibria steps can be found in other catalyzed reactions. One simple mechanism often encountered is shown in Equations (15) and (16):

$$\mathrm{R} + \mathrm{C} \Longleftrightarrow \mathrm{RC} \tag{15}$$

$$\mathrm{RC} + \mathrm{A} \xrightarrow{k_c} \mathrm{P} + \mathrm{C} \tag{16}$$

where the first step is a fast equilibrium and the second the rate-limiting step, k_c being the catalytic rate constant and C the catalyst. The reaction rate is given by Equation (17):

$$v = \frac{\mathrm{d[P]}}{\mathrm{d}t} = -\frac{\mathrm{d[A]}}{\mathrm{d}t} = k_c[\mathrm{RC}][\mathrm{A}] \tag{17}$$

The concentration of the intermediate complex, RC, can be obtained by applying the pre-equilibrium hypothesis as shown in Equation (18):

$$K = \frac{[\mathrm{RC}]}{[\mathrm{R}][\mathrm{C}]} \longrightarrow [\mathrm{RC}] = K[\mathrm{R}][\mathrm{C}] \tag{18}$$

from which the rate law can be given by Equation (19):

$$v = k_c K[\mathrm{R}][\mathrm{C}][\mathrm{A}] \tag{19}$$

Therefore, many complex reactions exhibit simple rate laws when the steady-state or the pre-equilibrium and limiting reaction steps hypothesis can be applied.

2.5 Determination of Simple Rate Laws

Most of the reactions of analytical interest follow the rate law given by Equation (5) after applying the steady-state or rate-limiting step approximations to the o.d.e. derived from their mechanisms. Generally, the study of the kinetics of a reaction involves measurement of a physical property like those summarized in Table 1. For this reason, it is convenient to express the rate law as a function of the measured physical property.

2.5.1 Expression of the Concentrations as a Function of a Physical Property

Let us assume that the kinetics of a reaction is monitored by measuring a physical property $S(t)$ that is a linear function of the composition of the reaction mixture given by Equation (20):

$$S = S_b + \sum_{i=1}^{N} s_i c_i \tag{20}$$

where N is the number of species in the system, S_b is the property measured from the blank and s_i is the proportionality coefficient between the concentration of the ith species and the physical property; the values of these constants can be estimated from equilibrium experiments when possible. The s coefficients are supposed to be independent of time and composition. If the rate law of the reaction is simple, the concentration variations will be described by a single extent of reaction, ξ, according to

Table 1 Physical properties commonly used to study the kinetics of a reaction

Physical property	Commentary
Light absorption (ultraviolet, visible, infrared)	Sensitive. Possibly the most frequently used physical property. Specially useful to follow fast kinetics
Light emission (fluorescence)	More specific and sensitive than light absorption. Allows following fast kinetics at the trace level
Electric conductivity	Little selectivity. The specific conductivity of ions is affected by the ionic environment and changes with the reaction mixture composition
Volume change	Little sensitivity. Only useful to follow slow reactions leading to the gelification or solidification of the reactive mixture
Pressure change	Property used to follow slow reactions in the gas phase
Rotation of the polarization plane of light	Property used to follow kinetics involving optically active species
Heat interchange	Little sensitivity and selectivity. Used to follow polymerization reactions or phase change kinetics
Multinuclear nuclear magnetic resonance absorption	Little sensitivity but selective. Used to follow slow organic reactions or some isomerization processes. Sensitive to the saturation of the signal. The property is not always linear

Equation (21):

$$c_i = c_{0,i} + \nu_i \xi \tag{21}$$

where $c_{0,i}$ is the initial concentration of ith species. The substitution of Equation (21) into (20) yields:

$$S = S_b + \sum_{i=1}^{N} s_i (c_{0,i} + \nu_i \xi)$$
$$= \left(S_b + \sum_{i=1}^{N} s_i c_{0,i} \right. + \left(\sum_{i=1}^{N} s_i \nu_i \right. \quad \xi = S_0 + S^0 \xi \tag{22}$$

where S_0 is the property value at zero time. From Equations (21) and (22), Equation (23) can be obtained:

$$\xi = \frac{S - S_0}{S^0} = \frac{c_i - c_{0,i}}{\nu_i} \tag{23}$$

At the end of the reaction, it becomes Equation (24):

$$\frac{S_\infty - S_0}{S^0} = \frac{c_{\infty,i} - c_{0,i}}{\nu_i} \tag{24}$$

where $c_{\infty,i}$ is the concentration of the ith species when the reaction has finished, and S_∞ the signal value at infinite time. From Equations (23) and (24), we obtain Equation (25):

$$\alpha = \frac{c_i - c_{\infty,i}}{c_{0,i} - c_{\infty,i}} = \frac{S_\infty - S}{S_\infty - S_0} \tag{25}$$

Let us call A the limiting reactant for which the final concentration, a_∞, is zero, then Equation (25) gives:

$$\alpha = \frac{a}{a_0} = \frac{S_\infty - S}{S_\infty - S_0} \tag{26}$$

Equation (26) is the basis of the data treatment of simple rate laws, because they can be expressed as a function uniquely of the α variable. It is important to realize that α is a dimensionless variable ranging from 0 to 1, and that it depends directly on the signal value.

2.5.2 First-order Reactions

For an elementary first-order reaction the stoichiometric equation will be given by Equation (27):

$$\mathrm{A} \xrightarrow{k} \mathrm{P} \tag{27}$$

and the corresponding differential rate equation by Equation (28):

$$\frac{\mathrm{d}a}{\mathrm{d}t} = -ka \tag{28}$$

where a is the concentration of reactant A at time t. After separating variables, this equation can be integrated as in Equation (29):

$$\int_{a_0}^{a} \frac{\mathrm{d}a}{a} = -\int_{0}^{t} k \, \mathrm{d}t \tag{29}$$

where a_0 is the concentration of reactant A at time zero. The integration yields Equation (30):

$$\ln\left(\frac{a}{a_0}\right. = \ln\left(\frac{S_\infty - S}{S_\infty - S_0}\right. = -kt \tag{30}$$

where Equation (26) has been used.

This expression can be rewritten as Equation (31) in terms of the variation of the physical property with time:

$$S = S_\infty - (S_\infty - S_0)\mathrm{e}^{-kt} \tag{31}$$

Finally, first-order reactions are characterized by a semi-reaction time ($t_{1/2}$, time needed to decrease the initial concentration of limiting reactant to half of its initial value) independent of the initial composition of the mixture, as shown in Equation (32):

$$t_{1/2} = \frac{\ln(2)}{k} \tag{32}$$

Many of the reactions of analytical interest can be treated as first-order reactions when experimental conditions are chosen adequately. For instance, a second-order reaction between reactants A and R behaves as a first-order reaction when one of the reactants, R, is present in excess ($[\mathrm{R}] \cong [\mathrm{R}]_0 \gg [\mathrm{A}]_0$) as shown in Equations (33) and (34):

$$\mathrm{A} + \mathrm{R} \xrightarrow{k_2} \mathrm{P} \tag{33}$$

$$\nu = k_2[\mathrm{R}][\mathrm{A}] \xrightarrow{[\mathrm{R}] \cong [\mathrm{R}]_0 \gg [\mathrm{A}]_0} \nu \cong k_2[\mathrm{R}]_0[\mathrm{A}] = k_1[\mathrm{A}] \tag{34}$$

In this case, we say that the second-order reaction has been transformed into a pseudo-first-order reaction. The ability to reduce the reaction order is a very valuable experimental tool, that often permits the simplification of the reaction kinetics.

2.5.2.1 Calculation of the Rate Constant The determination of the rate law for first-order reactions reduces to the calculation of the rate constant. The fitting of experimental data to Equation (35):

$$\ln(|S_\infty - S|) = \ln(|S_\infty - S_0|) - kt \tag{35}$$

gives the rate constant from the slope and, from the intercept, the initial concentration can be obtained. However, this method is not applicable when the final property cannot be accurately measured. This is the case for very slow reactions for which it is not

valuable to wait for completion, or when there are slow secondary processes which make it difficult to know the exact contribution of the main reaction to the value of S_∞. In such cases, it is recommended to use the methods developed by Guggenheim or Kezky–Mangerlsdorf–Swinbourne (KMS).[1]

For both methods the physical property is measured at two time series, $\{t_1, t_2, \ldots\}$ and $\{t_1 + \Delta t, t_2 + \Delta t, \ldots\}$, where Δt is a constant time increment. The *Guggenheim* method takes the differences between the physical properties measured in both series as shown in Equation (36):

$$S(t + \Delta t) - S(t) = (S_\infty - S_0)(1 - e^{-k\Delta t})e^{-kt} \quad (36)$$

This expression can be linearized by taking logarithms on both sides of the equation to give Equation (37):

$$\ln|S(t + \Delta t) - S(t)| = -kt + \ln[|S_\infty - S_0|(1 - e^{-k\Delta t})] \quad (37)$$

Thus, a fit of the logarithm of the difference in the physical property values versus time should give a line, from whose slope the rate constant can be calculated. In the least-squares fitting of Equation (37) it is recommended to use the weight as in Equation (38):

$$w(t) = [S(t + \Delta t) - S(t)]^2 \quad (38)$$

to correct the perturbation due to the logarithm linearization.[2]

The *KMS* method relates directly the data of both series, avoiding the signal difference calculation, as in Equation (39):

$$S(t + \Delta t) = S(t)e^{-k\Delta t} + S_\infty(1 - e^{-k\Delta t}) \quad (39)$$

Thus, a plot of $S(t + \Delta t)$ versus $S(t)$ yields a line with slope equal to $e^{-k\Delta t}$, from which it is possible to calculate the rate constant. In both methods the value of the time increment is an important factor, as illustrated in Figure 2. If Δt is small, the relative error in the signal difference will be large; on this basis, Δt should be as large as possible. However, the larger Δt the smaller the number of data points used; then, an intermediate Δt must be taken. It is recommended to take Δt between $t_{1/2}$ and $2t_{1/2}$.

Finally, data can be fitted to Equation (31) directly using a nonlinear method. In this case k, S_0 and S_∞ are adjustable parameters.

2.5.3 General Data Treatment for Simple Rate Laws

Let us suppose a reaction takes place according to Equation (1), and following the simple rate law given by Equation (40):

$$\frac{1}{\nu_A}\frac{da}{dt} = \frac{1}{\nu_R}\frac{dr}{dt} = -ka^p r^q \quad (40)$$

Figure 2 Average relative error (percentage) in the evaluation of a first-order rate constant ($k = 1\,s^{-1}$) using the Guggenheim (◇) and KMS ( ) methods, versus the Δt used.

where the stoichiometric coefficients are taken as positive, and p and q are the reaction orders with regard to the limiting reactant A and the co-reactant R, respectively. According to Equation (21), the concentrations of A and R are related by Equation (41):

$$r = r_0 - \frac{\nu_R}{\nu_A}(a_0 - a) = r_\infty + \frac{\nu_R}{\nu_A}a \quad (41)$$

The substitution of Equation (41) into Equation (40) leads to Equation (42):

$$\frac{da}{dt} = -\nu_A k a^p \left(r_\infty + \frac{\nu_R}{\nu_A}a\right)^q \quad (42)$$

This equation is commonly expressed as a function of the α variable defined in section 2.5.1. Taking into account that $\alpha = a/a_0$ yields Equation (43):

$$\frac{d\alpha}{dt} = -(\nu_A k a_0^{p+q-1})\alpha^p \left(\frac{r_\infty}{a_0} + \frac{\nu_R}{\nu_A}\alpha\right)^q \quad (43)$$

The benefits of this change of variable are evident; since we know how to relate the α value to a physical property, it will be possible to fit directly the measured property expressed in terms of α. In addition, the resulting differential equation has the dimensionless α as a unique variable, and analytical solutions for a large number of reaction orders, p and q, are tabulated.[3] Now, the rate law will be determined when the parameters k, p and q are known. Indeed, the rate law depends on the ratio of the stoichiometric coefficients; thus the study of the stoichiometry of the reaction must be done prior to the kinetic study. The objective of the next section is to give a review of methods allowing the determination of k, p and q.

2.5.4 Determination of the Reaction Orders and the Rate Constant

2.5.4.1 The Fractional Time Method The fractional time method[3] makes it possible to estimate the reaction orders and the rate constant from two kinetic experiments, one with the reactants being present initially at the stoichiometric ratio ($r_\infty = a_\infty = 0$), and the other carried out with excess of one of the reactants ($r_0 \gg a_0$, then $r_\infty/a_0 \gg \alpha$). In these cases, Equation (43) reduces to:

$$-\frac{\mathrm{d}\alpha}{\mathrm{d}t} = k^*\alpha^m \tag{44}$$

where k^* is a constant and $m = p + q$ in the first case, or $m = p$ in the second. The integration of Equation (44), when $m \neq 1$, leads to Equation (45):

$$\frac{1}{1-m}(1-\alpha^{1-m}) = k^*t \tag{45}$$

This method takes a series of pairs (t, α) covering a wide interval of α values [for instance $\alpha \in (0.1, 0.95)$], as shown in Equation (46):

$$\alpha_1 = f\alpha_0, \alpha_2 = f\alpha_1, \ldots, \alpha_j = f\alpha_{j-1}, \ldots, \alpha_n = f\alpha_{n-1} \tag{46}$$

where f is a constant in the interval $0 < f < 1$. Very often, some values will not be available because no measurements have been done, and, consequently, they will have to be interpolated, for instance by using the orthogonal polynomial method.[4]

Equation (47) shows the difference between two consecutive values of α, deduced from Equation (45):

$$\frac{1}{1-m}\left(\alpha_{j-1}^{1-m} - \alpha_j^{1-m}\right) = k^*(t_j - t_{j-1}) \tag{47}$$

which can be rearranged to Equation (48):

$$\alpha_j^{1-m}\frac{1-f^{m-1}}{k^*(1-m)} = (t_j - t_{j-1}) \tag{48}$$

On taking logarithms this leads to Equation (49):

$$\ln(t_j - t_{j-1}) = \ln\left(\frac{1-f^{m-1}}{k^*(1-m)}\right) + (1-m)\ln(\alpha_j) \tag{49}$$

A plot of the logarithm of $t_j - t_{j-1}$ versus the logarithm of α_j should yield a line whose slope and intercept give information on the value of m and the rate constant, respectively. Once the global order $p + q$ and the partial order p are known, the partial order q can be obtained by difference.

2.5.4.2 The Initial Rate Method The differential methods use the derivative of the physical property with respect to time, instead of the signal itself. The differential methods that use all the information (t, S) available are rarely applied because the numerical differentiation of all signal profile could increase remarkably the noise level. Nevertheless, the last affirmation is no longer true for experimental kinetic methods that measure the reaction rate directly as the electrochemical amperometric monitoring of an electrode reaction. An advantage of differential methods is that they do not need to integrate any differential equation since the reaction rates are dependent on the composition of the system through an algebraic equation system.

The initial rate method is a differential method that uses, as a dependent variable, the reaction rate at zero time, at which the composition of the system is known. Let us assume a reaction is taking place according to Equation (1). If the rate law is simple, the initial reaction rate is as shown in Equation (50):

$$v_0 = ka_0^p r_0^q \tag{50}$$

where the subscript "0" refers to zero time. Taking logarithms on both sides of the expression leads to Equation (51):

$$\ln(v_0) = \ln(k) + p\ln(a_0) + q\ln(r_0) \tag{51}$$

In this equation there are three parameters, k, p and q; thus it is necessary to measure at least three reaction rates to determine them by fitting Equation (51). The experimental design should be such that one initial concentration is kept constant whereas the other is changed and vice versa. In this way each set of data can be related independently to parameters p and q.

The correct evaluation of the initial rate is an important question. It can be estimated as the ratio between the variation of the signal and the interval of time elapsed at the beginning of the reaction. Therefore, for a first-order reaction given by Equation (52):

$$v_0^{\mathrm{est}} = \frac{S_2 - S_1}{t_2 - t_1} = (S_\infty - S_0)\frac{\mathrm{e}^{-kt_1} - \mathrm{e}^{-kt_2}}{t_2 - t_1} \tag{52}$$

The error associated can be calculated by means of a Maclaurin series expansion of the exponential term, shown in Equation (53):

$$\mathrm{e}^{-kt} = 1 - kt + \frac{1}{2}(kt)^2 - \cdots = \sum_{i=0}^{\infty}(-1)^i\frac{(kt)^i}{i!} \tag{53}$$

Since kt is close to zero near the origin, only the first three terms can be used, as shown in Equation (54):

$$v_0^{\mathrm{est}} \cong (S_\infty - S_0)k\left(1 + \frac{kt_1 + kt_2}{2}\right. \tag{54}$$

The exact initial rate can be evaluated by differentiating Equation (31) as shown in Equation (55):

$$v_0 = \left(\frac{\mathrm{d}S}{\mathrm{d}t}\right)_{t=0} = (S_\infty - S_0)k \tag{55}$$

Finally, the relative systematic error is given in Equation (56):

$$\varepsilon_r = \frac{v_0^{\mathrm{est}} - v_0}{v_0} = -\frac{kt_1 + kt_2}{2} \cong -\frac{\xi_{r1} + \xi_{r2}}{2} \tag{56}$$

where ξ_r is the relative extent of reaction, given by Equation (57):

$$\xi_r = \frac{a_0 - a}{a_0} = 1 - \mathrm{e}^{-kt} \tag{57}$$

and $\xi_r \cong kt$ for values of time small enough. Thus the relative systematic error will coincide with the average relative extent of reaction of the experimental points used to evaluate the initial rate.

Commonly, the signal values are not reliable close to the origin, due to the mixing effect and the induction period; therefore, a better approach is to fit the initial measured pairs (t, S) to an orthogonal polynomial series[5] from which the smoothed derivative is calculated and extrapolated at zero time.

The initial rate measurements are faster than those based on integral methods since the reaction is not required to reach completion, and can be applied to very slow reactions. Another advantage is that complications from side reactions are avoided. However, the mechanistic conclusions obtained about the reaction orders are only valid for the beginning of the reaction since these parameters can change, especially for reactions with complicated rate laws. Therefore, it is always highly recommended to complete the study with the aid of an integral method.

2.5.4.3 Use of Integrated Equations The use of the integrated rate equation is, maybe, the most popular technique to determine the rate constant. This method is acceptable once the reaction orders are known, because the integrated rate equation depends on the p and q values. When reaction orders are unknown, or if it is suspected that they can take fractional values, the methods given above are preferable, since in this case, the use of the integrated equation should be based on a trial and error method, and it is really difficult to distinguish between two close fractional values. Table 2 shows integrated equations[6] found frequently in the experimental work.

2.5.4.4 Mixed Simple–Complicated Equations Very often, it is found that reactions with complicated rate equations present a simple form for one of the reactants and a complicated form for the other. In this case, the rate law could be written as shown in Equation (58):

$$-\frac{\mathrm{d}a}{\mathrm{d}t} = f(r)a^p \tag{58}$$

where it was supposed that the kinetic behavior of reactant A was simple while reactant R presented a complicated form. In this situation, the kinetic study is carried out by running a reaction series where the reactant R is in excess.[7] Under these experimental conditions, where less than 1–10% of R is consumed, the rate law takes the simple form shown in Equation (59):

$$-\frac{\mathrm{d}a}{\mathrm{d}t} = f(r)a^p \approx f(r_0)a^p = k_{\mathrm{app}}a^p \tag{59}$$

Now, the techniques seen in the above sections enable us to find the reaction order with respect to the limiting reactant, but the dependence of the rate law on r must be deduced from a plot of k_{app} versus the initial concentration r_0.

A typical example is the dependence of most enzymatic reactions on pH; the rate presents a simple dependence on the substrate concentration, but the dependence on the proton concentration frequently exhibits a sigmoidal or bell-shaped curve explained by the acid–base pre-equilibria established among the enzyme, activated complex, and substrate with protons.

There is not a systematic procedure to deduce the mechanism of a reaction from its $k_{\mathrm{app}}(r_0)$ curve. Generally, several mechanisms are proposed based on additional information such as the structure of the products or the reactivity of the functional groups involved. Once the reaction mechanism has been derived, it is simplified on the basis of the steady state or the presence of pre-equilibria, and a rate law is obtained from which it is possible to get a theoretical equation for $k_{\mathrm{app}}(r_0)$, which is compared to the experimental data in order to calculate the more relevant kinetic parameters.

The procedure does not ensure the validity of a mechanism whose curve $k_{\mathrm{app}}(r_0)$ fits correctly the experimental one, but permits us to reject all mechanisms from which it is not possible to deduce a reasonable shape for $k_{\mathrm{app}}(r_0)$.

2.6 Treatment of Complex Mechanism

Complicated rate laws arise from complex reactions that need more than one differential equation and two or more extents of reaction to be described. For instance, the reaction used for the determination of oxygen peroxide with dichromate in acidic media[8] proceeds in two steps, the formation of the blue peroxychromic acid and its decomposition to yield aqueous Cr(III). The reaction mechanism consists of several elementary steps, and even

Table 2 Summary of integrated rate expressions for selected single reaction rate equations

p	q	Integrated rate law
0	0	$1-\alpha = ka_0^{-1}t$
$\frac{1}{2}$	0	$1-\alpha^{1/2} = \frac{k}{2}a_0^{-1/2}t$
1	0	$\ln\left(\frac{1}{\alpha}\right. = kt$
2	0	$\frac{1}{\alpha} - 1 = ka_0t$
0	$\frac{1}{2}$	$(1+c)^{1/2} - (\alpha+c)^{1/2} = \frac{k}{2}a_0^{-1/2}v^{1/2}t$
$\frac{1}{2}$	$\frac{1}{2}$	$\ln\ \frac{(1+c)^{1/2}+1}{(\alpha+c)^{1/2}+\alpha^{1/2}} = \frac{k}{2}v^{1/2}t$
0	1	$\ln\left(\frac{1+c}{\alpha+c}\right. = kvt$
1	1	$c>0, c<0$ $\ln\ \frac{\alpha+c}{\alpha(1+c)} = kca_0vt$
		$c=0$ $\frac{1}{\alpha} - 1 = ka_0vt$
0	2	$\frac{1}{a+c} - \frac{1}{1+c} = ka_0v^2t$
2	1	$c>0, c<0$ $\ln\ \frac{(1+c)\alpha}{\alpha+c} - c\left(1+\frac{1}{\alpha}\right. = c^{-2}ka_0^2vt$
		$c=0$ $\frac{1}{\alpha^2} - 1 = ka_0^2vt$
1	2	$c>0, c<0$ $\ln\ \frac{\alpha+c}{(1+c)\alpha} + c\left(\frac{1}{1+c} - \frac{1}{\alpha+c}\right. = c^{-2}ka_0^2v^2t$
		$c=0$ $\frac{1}{\alpha^2} - 1 = ka_0^2v^2t$

a, Concentration of limiting reactant A; a_0, r_0, initial concentration of species A and R; r_∞, final concentration of species R. $\alpha = a/a_0$, $c = r_\infty v_A/a_0v_R$.

applying the pre-equilibrium and the steady-state simplifications, it needs two reaction extent variables, one for the formation of the peroxychromic acid and the other for its decomposition, to describe all concentration variations.

Methods described in section 2.5 cannot be used for dealing with complex reactions with complicated rate laws, since the α variable relating the physical response and concentrations was deduced on the basis that a unique extent of reaction was needed.

The general data treatment of complex reactions, including those with complicated behavior, is carried out by developing a system of o.d.e.s from the reaction mechanism. The resolution of this system yields the theoretical concentration values, from which the monitored physical property can be estimated as a function of time. The comparison of estimated and experimental signal values by a regression method allows the model validity to be checked.

In section 3.3.2, several regression methods will be studied, but the next sections are devoted to describing methods capable of calculating the concentrations at any time from any reaction mechanism. Complex mechanisms can be conveniently divided into first-order mechanisms (first-order networks) and general mechanisms due to the different mathematical techniques that can be used to solve the o.d.e. system associated with first-order networks.

2.6.1 First-order Networks

A first-order network arises from reaction mechanisms made up entirely of first-order elementary steps. Typical

experiments leading to first-order complex mechanisms are those conducted under pseudo-first-order conditions, or those based on perturbation methods. The general o.d.e. system associated with these models is linear and takes the general form shown in Equation (60):

$$\frac{d\mathbf{c}}{dt} = \mathbf{A}\mathbf{c} \tag{60}$$

where $\mathbf{c}$ is a vector containing the species concentration, t is the reaction time, and $\mathbf{A}$ is a square $(N \times N)$ matrix, the elements of which are shown in Equation (61):

$$a_{ij} = k_{ji}, \quad a_{ii} = -\sum_{j=1}^{N} k_{ij} \tag{61}$$

where N is the number of species in the reaction system, and k_{ij} the rate coefficient for the reaction that converts i species into j species (many k_{ij} can have a zero value).

2.6.1.1 Integration of First-order Networks The first-order mechanisms are classified as reversible or irreversible. For the reversible mechanisms, the analytical solution is given by Equation (62):

$$c_i(t) = \sum_{j=1}^{N} u_{ij} g_j e^{\lambda_j t} \tag{62}$$

where c_i is the ith species concentration at time t, u_{ij} the elements of matrix $\mathbf{U}$ that contain the eigenvectors of matrix $\mathbf{A}$, λ_j being its jth eigenvalue, and g_j is a constant related to the initial conditions of the problem.

The reaction matrix $\mathbf{A}$ derived from a reversible network can be converted into a real symmetrical matrix, $\mathbf{A'}$, by applying the similarity transformation shown in Equation (63):

$$\mathbf{A'} = \mathbf{D}^{-1}\mathbf{A}\mathbf{D} \tag{63}$$

where $\mathbf{D}$ is a diagonal matrix containing the square root of the equilibrium concentrations of the species. The eigenvectors and eigenvalues of a symmetrical real matrix are always real and can be obtained by the simpler Jacobi's diagonalization method.[4] From the matrix $\mathbf{U'}$, containing the eigenvectors of matrix $\mathbf{A'}$, the matrix $\mathbf{U}$ is calculated as shown in Equation (64):

$$\mathbf{U} = \mathbf{D}\mathbf{U'} \tag{64}$$

The $\mathbf{g}$ vector ensures the compatibility of the general solution with the boundary conditions of the problem, and is calculated from the initial species concentration and the eigenvectors of $\mathbf{A}$. At zero time, Equation (62) gives Equation (65):

$$c_i(0) = \sum_{j=1}^{N} u_{ij} g_j \rightarrow \mathbf{c}(0) = \mathbf{U}\mathbf{g} \rightarrow \mathbf{g} = \mathbf{U}^{-1}\mathbf{c}(0) \tag{65}$$

This algorithm is faster than numerical methods and is not affected by the stiff nature of the kinetic system. Another advantage is that the calculation time is not affected severely by the number of experimental points.

The above method cannot be applied to an irreversible first-order mechanism because the reaction matrix $\mathbf{A}$, derived from an irreversible network, cannot be transformed into a real symmetrical matrix and it could have an incomplete set of eigenvalues. This leads to the reduction of exponential terms in Equation (36), and to the inclusion of polynomial terms, as illustrated in Table 3 for the consecutive mechanism when $k_1 = k_2$. Thus, for irreversible networks, the general solution for species concentration is given by Equation (66):

$$c_i(t) = \sum_{j=1}^{N} u_{ij} \frac{t^{m_j - 1}}{(m_j - 1)!} e^{\lambda_j t} \tag{66}$$

where m_j is the multiplicity of the jth eigenvalue of $\mathbf{A}$. Now, the Laplace transform technique[9] can be used to integrate irreversible first-order networks.[10]

This procedure is expected to work faster than numerical methods and is hardly dependent on the number of experimental points. The technique, however, needs more calculus time than the eigenvector method used for reversible networks, since the $\mathbf{U}$ matrix is calculated by solving N linear equation systems. This fact makes the procedure more size-dependent than the eigenvector method.

Table 3 Integrated rate laws for common first-order mechanisms[a]

Equilibrium reactions		
$A \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} B$	$a = a_0 \left\{1 - \frac{k_1}{k_1 + k_{-1}}[1 - e^{-(k_1 + k_{-1})t}]\right\}$	
	$b = a_0 \frac{k_1}{k_1 + k_{-1}}[1 - e^{-(k_1 + k_{-1})t}]$	
Consecutive reactions		
$A \xrightarrow{k_1} B \xrightarrow{k_2} C$	$a = a_0 e^{-k_1 t}$	
	$b = a_0 \frac{k_1}{k_2 - k_1}(e^{-k_1 t} - e^{-k_2 t})$	$k_1 \neq k_2$
	$b = a_0 k t e^{-kt}$	$k_1 = k_2$
	$c = a_0 - a - b$	
Parallel reactions		
$A \overset{k_1}{\longrightarrow} B$, $A \overset{k_2}{\longrightarrow} C$	$a = a_0 e^{-(k_1 + k_2)t}$	
	$b = a_0 \frac{k_1}{k_1 + k_2}[1 - e^{-(k_1 + k_2)t}]$	
	$c = a_0 \frac{k_2}{k_1 + k_2}[1 - e^{-(k_1 + k_2)t}]$	

[a] Initial concentrations for A, B, C were a_0, 0, 0 respectively.

2.6.2 Data Treatment of a General Kinetic Model

When reactions higher than first-order appear in the reaction mechanism, the o.d.e. shown in Equation (67) describes the general reaction system:

$$\frac{dc_n}{dt} = \sum_{i=1}^{R} \nu_{in} k_i \prod_{j=1}^{N} c_j^{\gamma_{ij}} \tag{67}$$

where N is the number of species in the system, R the number of reactions, k_i is the rate coefficient associated with the ith reaction, ν_{in} the stoichiometric coefficient of the nth species in the ith reaction, and γ_{ij} the reaction order of the jth species in the ith reaction. In order to generalize the problem, the reaction orders, γ_{ij}, can take any real number. However, if the reaction mechanism is used, only elementary steps are involved and the orders will be equal to the stoichiometric coefficients.

Frequently, the number of reactions is lower than the number of species, and the number of differential equations can be reduced by carrying out a change of variable. The new variables will be the extents of reaction, ξ, which are linearly related to the concentrations as shown in Equation (68):

$$c_n = c_{n,0} + \sum_{j=1}^{R} \nu_{nj} \xi_j \tag{68}$$

where $c_{n,0}$ is the initial concentration of the n species. The new o.d.e. is described by Equation (69):

$$\frac{d\xi_i}{dt} = k_i \prod_{n=1}^{N} \left(c_{n,0} + \sum_{j=1}^{R} \nu_{nj} \xi_j \right)^{\gamma_{in}} \tag{69}$$

Now the mathematical model is a system of R differential equations instead of N.

2.6.3 Numerical Integration of Kinetic Systems

The ordinary methods used to solve numerically o.d.e. systems are based on the calculation of a solution at time $t + h$ (where h is the integration step) from a solution known at time t, an integration scheme that is known as *explicit*. The value of h cannot be taken arbitrarily because it controls the accuracy at which the new solution is calculated and, thus, the stability of the integration procedure; small steps waste calculation time and increase the round-off error, and unreasonably large steps result in a diverging integration.

Several explicit integration methods can be applied to kinetic differential equation systems, such as the Runge–Kutta type methods or the predictor–corrector methods.[4] However, step size control is cumbersome, and high accuracy is difficult to obtain. A better approach for kinetic problems is to apply the explicit Taylor method,[11] which allows a direct and complete control of the step size.

The Taylor method is based on developing the solution as a polynomial series. It is clear that the solution at times t and $t + h$ are related by the Taylor formula shown in Equation (70):

$$\mathbf{c}^{(0)}(t+h) = \mathbf{c}^{(0)}(t) + \sum_{k=1}^{Q} \frac{h^k}{k!} \mathbf{c}^{(k)}(t) \tag{70}$$

where $\mathbf{c}$ is a vector containing the concentrations, and the superscripts in parentheses refer to the derivative order. It is obvious that this expression can be applied if the Q first derivatives are known. This task can be done as follows. The first derivative of the concentration of the nth species at time t is given by Equation (71):

$$c_n^{(1)} = \sum_{i=1}^{R} \nu_{in} \quad k_i \prod_{j=1}^{N} c_j^{\gamma_{ij}} \quad = \sum_{i=1}^{R} \nu_{in} \Phi_i^{(1)} \tag{71}$$

Thus, deriving the above expression $(k + 1)$ times yields Equation (72):

$$c_n^{(k+1)} = \sum_{i=1}^{R} \nu_{in} \Phi_i^{(k+1)} \tag{72}$$

where the $(k + 1)$th derivative of Φ_i can be calculated with the algorithm in Equation (73), derived from its own definition after applying the Leibniz rule:[12]

$$\Phi_i^{(k+1)} = \sum_{j=1}^{k} \binom{k-1}{j-1} \quad T_i^{(j)} \Phi_i^{(k+1-j)} \tag{73}$$

where $T_i^{(j)}$ is obtained from Equations (74) and (75):

$$T_i^{(j)} = \sum_{n=1}^{N} \gamma_{in} f_n^{(j)} \tag{74}$$

$$f_n^{(j)} = \frac{c_n^{(j)}}{c_n^{(0)}} - \sum_{i=1}^{j-1} \binom{k-1}{i-1} \quad f_n^{(i)} \frac{c_n^{(j-i)}}{c_n^{(0)}} \tag{75}$$

The recurrent algorithm starts with the values shown in Equation (76):

$$f_n^{(1)} = \frac{c_n^{(1)}}{c_n^{(0)}}, \quad T_i^{(1)} = \sum_{n=1}^{N} \gamma_{in} f_n^{(1)} \tag{76}$$

The Taylor method allows the integration error to be controlled in a straightforward way. Equation (70) indicates that the error committed in the calculation of nth concentration at time $t + h_n$ is given by the $Q + 1$ term in the Taylor series shown in Equation (77):

$$O_n(h_n) = \frac{h_n^{Q+1}}{(Q+1)!} c_n^{(Q+1)} \tag{77}$$

It is desirable that the relative error is below a given value:

$$O_n(h_n) \leq \varepsilon c_n^{(0)} \tag{78}$$

The combination of Equations (77) and (78) affords the desired result:

$$h_n \leq \left\{ \varepsilon (Q+1)! \ \frac{c_n^{(0)}}{c_n^{(Q+1)}} \right\}^{\frac{1}{Q+1}} \tag{79}$$

Finally, as each species requires its own step, convergence is ensured by taking the smallest integration step as given in Equation (80):

$$h = \min(h_n) \tag{80}$$

This method has been shown to be better than other explicit methods for accurately integrating nonstiff and moderately stiff kinetic models,[11] and it can be modified[13] to cope with stiff systems.

The stiffness of a kinetic problem arises from mechanisms where steps coexist with very different rates. This drastically slows down the numerical integration process, because the integration step depends inversely on the rate constants. Thus, the existence of fast processes implies a small step slowing down the whole integration procedure. Stiffness is a serious problem because the nonlinear least-squares (NLS) minimization routines could need the o.d.e. system to be integrated several thousands of times, and during the minimization process there is a high probability of finding a stiff area. If such an event occurs and a nonstiff integration method is being used, the minimization procedure will suddenly slow down, taking much more time to complete a minimization cycle.

For first-order o.d.e. systems, stiffness can be solved by a change of variable that can decouple the o.d.e. systems. Then each o.d.e. can be integrated separately. This is the strategy followed by the methods shown in section 2.6.1.1. However, the situation is rather more complicated for nonlinear o.d.e. systems where this procedure is not operative.

It has been well established that the integration routines able to solve stiff problems should be based on implicit or semi-implicit numerical methods.[14] That means that the knowledge of the solution of the o.d.e. at time $t + h$ is obtained by solving an algebraic equation system, whose unknown variables are, precisely, the o.d.e. solutions. The procedure presents obvious advantages for stiff systems that can be solved in a short space of time, but implicit methods are much more complex and have disadvantages when they are applied to nonstiff problems due to the time employed in solving the algebraic system. In such cases, a waste of calculation time and a relatively poor accuracy in the numerical solution could be observed. There are several types of algorithms available to solve stiff o.d.e. systems,[4] including the *Bader–Deuflhard* algorithm and the *Gear* method. Also an *implicit Taylor* method can be developed to obtain precise solutions for nonlinear stiff systems.

3 ERROR ANALYSIS IN CHEMICAL KINETIC METHODS

The study of sources of error and their effects on results is an essential part of data treatment. Errors can be divided into random and systematic. In this section, random errors are those inherent to the measurement process, affecting the results in an unpredictable way, and they can be averaged away using enough data. Random errors can be quantified by the standard deviation of the results.

However, systematic errors arise mainly from uncontrolled changes in the factors that modify the reaction rate, and from the simplifications made in the mathematical models. This kind of error will not average away using any amount of data. Sources of systematic errors must be carefully controlled because it is difficult to detect this kind of error.

3.1 Factors Influencing the Reaction Rate

The reaction rate, and therefore most of the kinetic methods, are strongly dependent on several factors such as temperature, reactant concentration, ionic strength, and solvent nature. The reaction rate can be adjusted to a practical range controlling these factors. However, variations out of control can lead to important systematic errors.

The Arrhenius equation shown in Equation (81) is an empirical relationship describing the dependence of the rate constant, k, on the absolute temperature, T:

$$k = A\mathrm{e}^{-\frac{E_a}{RT}} \tag{81}$$

where E_a is the activation energy, with dimensions of energy per mole, A is the pre-exponential factor having the units of k, and R is the universal gas constant ($8.31\,\mathrm{J\,K^{-1}\,mol^{-1}}$).

For many homogeneous reactions, the activation energy ranges between 50 and $100\,\mathrm{kJ\,mol^{-1}}$, and thus, the rate constant increases by a factor of 2–4 per 10 °C rise in room temperature. For instance, a temperature variation of 0.1 °C produces a 1% change in the rate constant at room temperature for a reaction having an activation energy of $75\,\mathrm{kJ\,mol^{-1}}$.

The reactant concentration has a proportional effect on the reaction rate. For a pseudo-first-order reaction, the kinetic constant is directly proportional to the reagent concentration as shown in Equation (82):

$$k_1 = k_2[\mathrm{R}] \tag{82}$$

Therefore, the concentration errors are correlated with those of the reaction rate.

The simplest treatment to quantify the influence of ionic strength on the reaction rate is based on the transition-state theory. This theory considers that a fast pre-equilibrium step is established among reactants and the activated complex as shown in Equation (83):

$$\mathrm{A} + \mathrm{R} \Longleftrightarrow \mathrm{AR}^{\#} \longrightarrow \mathrm{P} \tag{83}$$

The reaction rate of this system is given by Equation (84):

$$v = k[\mathrm{AR}^{\#}] = kK^{\#}\frac{\gamma_{\mathrm{A}}\gamma_{\mathrm{R}}}{\gamma_{\mathrm{AR}^{\#}}}[\mathrm{A}][\mathrm{R}] \tag{84}$$

where $K^{\#}$ is the thermodynamic equilibrium constant for the formation of the activated complex, and γ_{A}, γ_{R}, and $\gamma_{\mathrm{AR}^{\#}}$ the activity coefficients of the species. The activity coefficient can be related to the ionic strength, I, by the extended Debye–Hückel equation:

$$\log \gamma_i = -\frac{AZ_i^2\sqrt{I}}{1 + a_iB\sqrt{I}} + b_iI \tag{85}$$

where Z_i is the charge of the ith species, and b_i becomes significant for neutral species or high ionic strengths. Considering that the product a_iB is usually taken as unity, and that $Z_{\mathrm{AR}^{\#}} = Z_{\mathrm{A}} + Z_{\mathrm{R}}$, substitution of the activity coefficients in Equation (84) by the expression in Equation (85) leads to Equation (86):

$$\log k = \log k_0 + \frac{2AZ_{\mathrm{A}}Z_{\mathrm{R}}\sqrt{I}}{1 + \sqrt{I}} + bI \tag{86}$$

where k_0 is the rate constant at zero ionic strength. This expression indicates that changes in the ionic strength scarcely affect the rate of reactions taking place between neutral species, or an ion and a neutral molecule, since the product $Z_{\mathrm{A}}Z_{\mathrm{R}}$ cancels out and b is usually small. In addition, the rate of a second-order reaction between equally charged ions should increase as the ionic strength increases, whereas the rate of a reaction between oppositely charged ions should decrease. For instance, an increase of ionic strength from 0.01 to 0.011 produces a 1% change in the rate constant for a reaction taking place between monocharged ions. The effect is considerably higher for low ionic strengths; thus, a change of 7% is observed when the ionic strength increases from 0 to 0.001.

The rate of a chemical reaction can be modified by the nature of the solvent. In spite of its complexity, Equation (87) shows that a linear variation in $\ln(k)$ with the inverse of the dielectric constant of the solvent, $1/\varepsilon$, is observed with reasonable accuracy:[15]

$$\ln k = \ln k_0 + m\frac{1}{\varepsilon} \tag{87}$$

where k_0 is the rate constant in a medium of infinite ε, and m a constant depending on temperature, charge, ionic radius, and the dipole moments of reactants and activated complex. Equation (87) suggests that an increase in solvent polarity favors those reactions where an activated polar complex is formed, and slows down those reactions occurring through a nonpolar activated complex. Hence, the solvent has a drastic influence on the rate constant. For instance, the reaction rate of triethylamine with ethyl iodide suffers a 4200% increase when changing from benzene to acetonitrile.[1]

Finally, it could be of interest to compare equilibrium and rate measurements. According to the relationship in Equation (88) relating the equilibrium constant to the forward and reverse rate constants:

$$K = \frac{k_{\mathrm{f}}}{k_{\mathrm{r}}} \tag{88}$$

the effect of the experimental conditions might be lower on the equilibrium constant than on the rate constants due to the compensation of errors in Equation (88). Therefore, in order to obtain good results with kinetic-based methods, the experimental conditions must be controlled more carefully than is usual in the equilibrium-based methods.

3.2 Methods Based on First-order Reactions for the Determination of One Species

From a practical analytical viewpoint, most kinetic methods for the determination of a single species are carried out in pseudo-first-order conditions. Table 4 shows the most frequently used experimental conditions in uncatalyzed, catalyzed, and enzymatic methods in order to assure pseudo-first-order kinetics. Depending on the original mechanism, the pseudo-first-order rate constant will be a function of several experimental factors, such as the reagent concentration. The rate law in Equation (89) summarizes the different cases in a general form:

$$v = \frac{\mathrm{d}[\mathrm{A}]}{\mathrm{d}t} = -(k_{\mathrm{c}}[\mathrm{C}]_0 + k_{\mathrm{u}}[\mathrm{R}]_0)[\mathrm{A}] = -k[\mathrm{A}] \tag{89}$$

where k_{c} and k_{u} are rate constants for the catalyzed and uncatalyzed reactions, respectively. On integration Equation (89) leads to Equation (90):

$$[\mathrm{A}] = [\mathrm{A}]_0\mathrm{e}^{-kt} = [\mathrm{A}]_0\mathrm{e}^{-(k_{\mathrm{c}}[\mathrm{C}]_0 + k_{\mathrm{u}}[\mathrm{R}]_0)t} \tag{90}$$

Now, after taking into account the linear dependency of the response upon concentration given by Equation (31)

Table 4 Mechanisms frequently used in kinetic analysis and common simplifications

Reaction type	Mechanism	Original o.d.e.	Simplification	Applied o.d.e.
Uncatalyzed	$A + R \xrightarrow{k_2} P$	$\frac{d[P]}{dt} = k_2[R][A]$	$[R] \gg [A]; [R] \approx [R]_0$	$v = k_2[R]_0[A]$
Catalyzed	$S + R \xrightarrow{k_u} P$ $R + C \Longleftrightarrow I$ $I + S \xrightarrow{k_c} P + C$	$\frac{d[P]}{dt} = k_c[I][S] + k_u[R][S]$	$[R] \gg [S]$ $[R] \approx [R]_0$ $[I] \approx [C]_0$	$v = (k_c[C]_0 + k_u[R]_0)[S]$
Enzymatic	$S + E \Longleftrightarrow ES \xrightarrow{k_2} P + E$	$\frac{d[P]}{dt} = \frac{k_2[E]_0[S]}{K_m + [S]}$	$[S] \ll K_m$ $[S] \gg K_m$	$v = \frac{k_2}{K_m}[E]_0[S]$ $v = k_2[E]_0$

for first-order reactions, we can write Equation (91):

$$S = S_\infty - s[A]_0 e^{-kt} = S_0 + s[A]_0(1 - e^{-kt}) \quad (91)$$

where s is a linear combination of the proportionality constants of the different species with signal. For instance, $s = s_P - s_A - s_R$ for the reaction $A + R \longrightarrow P$.

Data treatment can be done by applying several strategies.[16] The different data used by each treatment appear in the kinetic profile shown in Figure 3. In the fixed time method the signal values S_1 and S_2 are measured at constant times t_1 and t_2. On the contrary, in the variable time method the time values are measured, whereas the signal values remain constant. In the initial rate method, initial rate, v_0, is measured as the slope, near the origin, of the kinetic curve. Finally, the predictive kinetic (PK) method[17] is based on the extrapolation of a fitted kinetic profile to the predicted final signal, S_∞.

Figure 3 Signal–time profile for a first-order reaction. Some data treatment used in kinetic methods are shown.

3.2.1 *Implicit Systematic Errors of the Data Treatment*

The fixed and variable time methods are based on the change of the signal during a time interval Δt. For a first-order reaction we obtain Equation (92):

$$\frac{\Delta S}{\Delta t} = s[A]_0 \frac{e^{-kt_1} - e^{-kt_2}}{t_2 - t_1} = s[A]_0 e^{-kt_1} \frac{1 - e^{-k\Delta t}}{t_2 - t_1} \quad (92)$$

where $t_2 = t_1 + \Delta t$. The expansion of the exponential function in a Maclaurin series, Equation (53), yields Equation (93):

$$\frac{\Delta S}{\Delta t} = sk[A]_0 e^{-kt_1} \sum_{i=1}^{\infty} (-1)^i \frac{(k\Delta t)^{i-1}}{i!} = k[A]_0\Omega$$
$$= (k_c[C]_0 + k_u[R]_0)[A]_0\Omega \quad (93)$$

where Ω is a calibration factor depending on the products kt_1 and kt_2.

The determination process can be divided into the calibration and the sample measurement steps. The calibration step allows us to calculate the value of Ω from standards of known concentration. This value will be used in the determination of analyte concentration in the sample. The result will fit to the real concentration, when the factor Ω remains constant between the calibration and the sample measurements. Taking t_1 the closest to zero reduces the error and increases the sensitivity. On the other hand, the more similar the calibration and sample concentrations, the closer the Ω values. The data treatment also has an important effect. When the initial concentration of the limiting reagent, A, is determined, the rate constant remains invariable between the calibration procedure and the sample determination. Thus, Ω will keep constant for the fixed time method, but not for the variable time method, and a systematic error will be produced. This situation is also applicable to

the determination of substrate concentration in enzyme-catalyzed reactions which exhibit a similar pseudo-first-order kinetic behavior, as shown in Table 4.

When a catalyst is determined, the rate constant will change between the standards and the sample, and thus Ω will vary for the fixed time method, introducing a systematic error. However, the product kt will remain constant for the variable time method, since this quantity is related to the signal as Equation (94) shows:

$$kt = -\ln\left(\frac{S_\infty - S}{S_\infty - S_0}\right) \tag{94}$$

where S, S_∞, and S_0 are constants, making Ω invariable. The same situation is found for uncatalyzed reactions when the species to be determined is the reagent in excess, R, but now a small systematic error is committed when R affects the signal value.

Another approach, shown in Equation (95), takes the logarithm of the signal ratio:

$$\frac{1}{\Delta t}\ln\frac{S_\infty - S_1}{S_\infty - S_2} = k = k_c[C]_0 + k_u[R]_0 \tag{95}$$

In this case, the fixed time method can be used without systematic error when S_∞ is known. When it is unknown, and the logarithm of the signal ratio is used, Equation (96) is obtained:

$$\ln\frac{S_1}{S_2} = k\Delta t + \ln\frac{S_\infty e^{kt_1} - S_\infty + S_0}{S_\infty e^{kt_2} - S_\infty + S_0} \tag{96}$$

Now, a systematic error is expected, but smaller than that obtained using ΔS, because of the quotient error compensation in Equation (96).

Figure 4 shows the performance of the fixed and variable time methods. According to the above conclusions, the variable time method will give the best results when a catalyst is determined, whereas the fixed time method will be superior for the determination of the limiting reagent for uncatalyzed reactions.

Ingle and Crouch[18] have also shown that the variable time methodology has a wider range of catalyst concentration amenable to determination, in spite of the difficulty involved in developing a general treatment, owing to the large variety of possible mechanisms encountered. Furthermore, the authors concluded, on the basis of a study of the theoretical and experimental factors influencing the accuracy of reaction rate measurements, that the variable time approach is superior in most cases where nonlinear response curves are obtained.

A different approach can be applied by fitting the whole kinetic curve to the integrated equation to obtain k and $[A]_0$. When the rate constant is the analytical parameter, the method of tangents can be used. In this method, the linear fit of Equation (35) yields, as the slope, the rate constant, which is linearly related to the catalyst concentration. When the final signal is unknown, the Guggenheim or KMS methods should be used as illustrated in section 2.5.2.1. Finally, since the method of tangents performs more measurements to obtain the rate constant, its application is expected to result in better precision than the variable or fixed time methods. However, the method of tangents is highly affected by model nonlinearities and fails when the kinetics is complex, and the integration of the rate equations is difficult or impossible.

Figure 4 Variation of the mean relative error of the data used in the determination of two samples of 2.5 and 3.5 μM, with increasing extent of reaction. A calibration of five points (1, 2, 3, 4 and 5 μM) and the following conditions were applied: ( ) fixed time and (◇) variable time, for the uncatalyzed determination of a substance using a pseudo-first-order reaction with $[R]_0 = 50\,\mu M$ and $k = 0.1\,s^{-1}\,\mu M^{-1}$; (■) fixed time and ( ), variable time for the determination of a catalyst with $k_c = 1.0$ and $k_u = 0\,s^{-1}\,\mu M^{-1}$.

When the initial concentration of the limiting reagent is to be determined, the PK method can be applied. The method is based on the extrapolation of a fitted kinetic profile to predict the signal at the end of the reaction. The advantage of this approach is the bypassing of errors due to experimental changes in k that go with changes in temperature, reagent concentration, or ionic strength. Two approaches can be used, the consecutive linear determination of k and $[A]_0$, or the simultaneous nonlinear determination of k, $[A]_0$, and S_0, based on Equation (91). Baeza-Baeza et al.[19] evaluated several methods for the determination of an analyte following pseudo-first-order kinetics, and observed that the PK method gave the best results, specially when the average

rate constant of all kinetic runs is used instead of the individual ones. This fact indicates that random errors in the constant have an important effect on the extrapolated final signal; this effect decreases when the extent of the reaction increases, that is, as the extrapolation risk decreases.

The rate methods are differential approaches based on the relation of the reaction rate with concentration as shown in Equation (97):

$$v = \frac{\mathrm{d}S}{\mathrm{d}t} = sk[\mathrm{A}]_0 \mathrm{e}^{-kt} \tag{97}$$

The initial rate method is based on the measurement of the slope of the kinetic curve at initial times, as is shown in Equation (54). As stated by Equation (56), the smallest possible error is obtained when the measurement is made as close to the origin as the mixing time and induction period permit. It is recommended that no more than 2% reactant conversion be allowed to occur. In addition, a reduction in the systematic error can be done if the initial rate is obtained by fitting the initial values of the signal to an orthogonal polynomial series.

On the other hand, an error compensation occurs between calibration and determination in the global process. Therefore, bearing in mind that Equation (54) is a simplified version of Equation (93), similar conclusions to those previously outlined will be obtained when the model follows first-order kinetics near the origin. However, for catalyzed reactions, including enzymatic ones, the initial kinetics could not follow a first-order model owing to the induction period necessary to reach the stationary state. The advantages generally attributed to initial rate measurements include the minimal complications from side reactions, and the increased sensitivity over other rate measurements, since the exponential value in Equation (97) is unity when $t = 0$. Finally, it should be realized that the success of the initial rate measurements depends greatly on the availability of sufficiently sensitive and reproducible monitoring of small signal changes.

A special case is found in the determination of the enzyme activity because, as shown in Table 4, the reaction follows a zero-order law under saturation conditions. In order to study the error of this treatment, an integration of the Michaelis–Menten equation must be done.[20] A good approximation is to suppose that $[\mathrm{S}] \cong [\mathrm{S}]_0 - [\mathrm{P}]$ when $[\mathrm{S}]_0 \gg [\mathrm{E}]_0$; now, considering that the signal is produced by the product of the reaction, $S = s_\mathrm{P}[\mathrm{P}]$, the integrated equation has the form shown in Equation (98):

$$S = s_\mathrm{P} k_2 [\mathrm{E}]_0 t - s_\mathrm{P} K_\mathrm{m} \ln\left(\frac{S_\infty}{S_\infty - S}\right. \tag{98}$$

This expression allows signal and time variations to be related as shown in Equation (99):

$$\frac{\Delta S}{\Delta t} = s_\mathrm{P} k_2 [\mathrm{E}]_0 - s_\mathrm{P} K_\mathrm{m} \frac{\ln[(S_\infty - S_1)/(S_\infty - S_2)]}{\Delta t} \tag{99}$$

The final signal, S_∞, is expected to be large compared to S_1 and S_2 due to the saturation conditions, and, thus, the logarithm can be expanded by means of a Taylor series to Equation (100):

$$\ln\left(\frac{S_\infty - S_1}{S_\infty - S_2}\right. \quad \cong \frac{S_2 - S_1}{S_\infty - S_2} = \frac{\Delta S}{S_\infty - S_2} \tag{100}$$

leading to Equation (101):

$$\frac{\Delta S}{\Delta t} = \frac{s_\mathrm{P} k_2 (S_\infty - S_2)}{S_\infty - S_2 + s_\mathrm{P} K_\mathrm{m}} [\mathrm{E}]_0 = m[\mathrm{E}]_0 \tag{101}$$

Thus, if the variable time method is applied, the slope, m, will remain constant since S_2 has a constant value. On the other hand, S_2 varies in the fixed time method, and m is not constant, resulting in a systematic error. Figure 5 shows the application of both methods to the enzymatic activity determination by using an increasing time interval. The variable time method gives better results when the extent of the reaction is high enough to ensure the validity of the stationary state and the Michaelis–Menten equation. However, this hypothesis is not valid at the beginning of

Figure 5 Variation of the mean relative error of the data used with increasing extent of reaction in the determination of two enzyme concentrations (2.5 and 3.5 nM), applying the fixed time (◇) and the variable time ( ) approach. A calibration of five points (1, 2, 3, 4 and 5 nM) was used. The kinetic constants of the Michaelis–Menten mechanism were $k_1 = 50$, $k_{-1} = 20$, $k_2 = 200$ and $[\mathrm{S}]_0 = 1\,\mu\mathrm{M}$.

the reaction. The fixed time method improves itself as the time interval decreases, approaching the data treatment of the initial rate method, whereas the variable time method gives worse and worse results because it evaluates the initial rate at different times. It must be realized that the reaction rate increases almost linearly with time at the beginning of reaction, as shown in Equation (102):

$$v_{t\to 0} = k_2[\mathrm{ES}]_{t\to 0} \cong \frac{k_2 k_1}{k_{-1}+k_2}[1-\mathrm{e}^{-(k_{-1}+k_2)t}][\mathrm{S}]_0[\mathrm{E}]_0 \cong k_2 k_1 t[\mathrm{S}]_0[\mathrm{E}]_0 \tag{102}$$

where $[\mathrm{ES}]_{t\to 0}$ has been obtained by integration of Equation (10) supposing that S and E concentrations remain constant and equal to their initial values. Thus, the fixed time method will yield better results near $t = 0$.

3.2.2 *Propagation of Systematic Errors*

The study of the sources of systematic errors can lead to an optimum experimental design minimizing the error propagation. Systematic errors can arise from changes in the rate constant between calibration and sample determination, owing to variations in the factors that affect the reaction rate.

When the fixed-time method is applied to an uncatalyzed reaction, the linear calibration model will be as shown in Equation (103):

$$\Delta S = m[\mathrm{A}]_0 + n \tag{103}$$

where m and n are the calibration parameters. A systematic error in the rate constant, ε_k, will cause the systematic error given in Equation (104) for the initial concentration of the analyte:

$$\varepsilon_\mathrm{A} = \frac{\partial \Delta S}{\partial k}\frac{\varepsilon_k}{m} = s[\mathrm{A}]_0(t_2\mathrm{e}^{-kt_2} - t_1\mathrm{e}^{-kt_1})\frac{\varepsilon_k}{m} \tag{104}$$

The error will be zero if the times are chosen according to Equation (105):

$$t_1\mathrm{e}^{-kt_1} = t_2\mathrm{e}^{-kt_2} \tag{105}$$

The function $t\mathrm{e}^{-kt}$ has a bell shape with a maximum at $t = 1/k$. As time moves away from this value, the function decreases. As a consequence, the optimal approach consists of choosing the biggest t_2 possible to lower the $t\mathrm{e}^{-kt}$ function, and resolving Equation (105) for t_1.

When a catalyzed reaction is treated by the variable time approach, the analytical function is $1/\Delta t$, and the error is given by Equation (106):

$$\varepsilon_\mathrm{C} = \frac{\partial(1/\Delta t)}{\partial k_\mathrm{c}}\frac{\varepsilon_{k_\mathrm{c}}}{m} = \frac{[\mathrm{C}]_0}{\ln[(S_\infty - S_1)/(S_\infty - S_2)]}\frac{\varepsilon_{k_\mathrm{c}}}{m} \tag{106}$$

In this case, the error decreases when ΔS increases, since the logarithm also increases.

Regarding the initial rate method, taking into account that in this case $m = sk$, its application leads to a constant error as shown in Equation (107):

$$\varepsilon_\mathrm{A} = \frac{\partial(v_0)}{\partial k}\frac{\varepsilon_k}{m} = s[\mathrm{A}]_0\frac{\varepsilon_k}{m} = [\mathrm{A}]_0\frac{\varepsilon_k}{k} \tag{107}$$

Thus, the relative error in k propagates invariable to the relative concentration error. Holler et al.[21] studied the propagation of errors in the instantaneous rate measurement. From Equation (97) is obtained Equation (108):

$$\varepsilon_\mathrm{A} = \frac{\partial(v)}{\partial k}\frac{\varepsilon_k}{m} = s[\mathrm{A}]_0(1-kt)\mathrm{e}^{-kt}\frac{\varepsilon_k}{m} = [\mathrm{A}]_0(1-kt)\frac{\varepsilon_k}{k} \tag{108}$$

This expression shows that the reaction rate values are independent of changes in parameters affecting the value of the rate coefficient at a time equal to $1/k$. Besides, when the initial rate is measured, time equals zero and the propagated error is one of the largest.

The precision in the determination of an analyte by using the PK extrapolation method depends significantly on the extent of the reaction concerned. Let us suppose that an extrapolation is carried out using only one data point as in Equation (109):

$$[\mathrm{A}]_0 = \frac{S - S_0}{s(1-\mathrm{e}^{-kt})} \tag{109}$$

From Equation (109) it is clear that the error in $[\mathrm{A}]_0$ due to an error committed in k is given by Equation (110):

$$\varepsilon_\mathrm{A} = \frac{\partial[\mathrm{A}]_0}{\partial k}\varepsilon_k = -\frac{[\mathrm{A}]_0 t\mathrm{e}^{-kt}}{1-\mathrm{e}^{-kt}}\varepsilon_k \tag{110}$$

Now, taking into account that the extent of reaction is $\xi = 1 - \mathrm{e}^{-kt}$, the relative error in $[\mathrm{A}]_0$ will be as shown in Equation (111):

$$\varepsilon_{r_\mathrm{A}} = \frac{1-\xi}{\xi}[\ln(1-\xi)]\varepsilon_{r_k} \tag{111}$$

Carr[22] studied this effect showing that the relative precision improves monotonically with increasing ξ, and that the relative uncertainty in $[\mathrm{A}]_0$ tends to the relative uncertainty in k at small values of ξ; finally, when the reaction approaches completion ($\xi \to 1$), the uncertainty in the measurement of k causes no appreciable systematic error in the estimated concentration.

Another kind of systematic error arises from the presence of an interferent species, B, in the sample. In this case, the variation of the signal in the sample for an uncatalyzed reaction is given by Equation (112):

$$\Delta S = s_\mathrm{A}[\mathrm{A}]_0(\mathrm{e}^{-k_\mathrm{A}t_1} - \mathrm{e}^{-k_\mathrm{A}t_2}) + s_\mathrm{B}[\mathrm{B}]_0(\mathrm{e}^{-k_\mathrm{B}t_1} - \mathrm{e}^{-k_\mathrm{B}t_2}) \tag{112}$$

The relative error in the determination of A, supposing the calibration standards are free of B, and applying the fixed time method, is given by Equation (113):

$$\varepsilon_{r_A} = \frac{s_B}{s_A}\frac{[B]_0}{[A]_0}\frac{e^{-k_B t_1} - e^{-k_B t_2}}{e^{-k_A t_1} - e^{-k_A t_2}} \tag{113}$$

This expression shows that the error increases when k_B increases and decreases when t_1 and Δt decrease. Obviously, error decreases with s_B and $[B]_0$.

The error of the variable time method for a catalyzed reaction with interference from another catalyst is given by Equation (114):

$$\varepsilon_{r_C} = \frac{[B]_0}{[C]_0}\frac{k_C}{k_B} \tag{114}$$

where the error depends only on the reaction rates and the initial concentration ratio. If the rate method has been used, the error will be as shown in Equation (115):

$$\varepsilon_{r_A} = \frac{s_B}{s_A}\frac{k_B}{k_S}\frac{[B]_0}{[A]_0}\frac{e^{-k_B t}}{e^{-k_A t}} \tag{115}$$

which is a minimum at $t = 0$, that is, for the initial rate method.

3.2.3 Propagation of Random Errors

The error propagation theory must be applied to obtain the parameter uncertainty due to random errors. For small independent errors in the variables, the propagation error rule is given by Equation (116):

$$\sigma_y^2 = \sum \left(\frac{\partial y}{\partial x_i}\right)^2 \sigma_{x_i}^2 \tag{116}$$

When an uncatalyzed reaction is used to determine the concentration of a substance by applying the fixed time method with, for simplicity, a unique calibration point, the result is given by Equation (117):

$$[A]_{sm} = \frac{\Delta S_{sm}}{\Delta S_{cl}}[A]_{cl} \tag{117}$$

where the subscript "sm" refers to the sample and "cl" to the calibration measurements. The mean square relative error of the concentration is given by Equation (118):

$$\frac{\sigma_A^2}{[A]_{sm}^2} = \frac{\sigma_{\Delta S_{sm}}^2}{\Delta S_{sm}^2} + \frac{\sigma_{\Delta S_{cl}}^2}{\Delta S_{cl}^2} \tag{118}$$

This expression indicates that the relative square error in the evaluated concentration is the addition of the relative square error of the measured signal differences. The variance of the measured signal is given by Equation (119):

$$\sigma_{S_i}^2 = \sigma_S^2 + \left(\frac{\partial S_i}{\partial t}\right)^2 \sigma_t^2 \tag{119}$$

The signal is affected by its own uncertainty, σ_S^2, and by the uncertainty introduced for the lack of precision in time.

Now, supposing homocedastic data, Equation (120) is obtained:

$$\frac{\sigma_{\Delta S}^2}{\Delta S^2} = \frac{\sigma_{S_1}^2 + \sigma_{S_2}^2}{\Delta S^2} = 2\frac{\sigma_S^2}{\Delta S^2} + \frac{(S_\infty - S_2)^2 + (S_\infty - S_1)^2}{\Delta S^2}k^2\sigma_t^2 \tag{120}$$

The uncertainty decreases as ΔS increases, reaching a minimum when S_2 tends to S_∞, and S_1 tends to the smallest signal value. On the other hand, the error increases as the reaction rate increases, owing to the higher uncertainty in the signal measurement produced by the time uncertainty.

When the variable time method is used to determine the concentration of catalyst C, the relative square error in the concentration is a function of the time interval measured as shown in Equation (121):

$$\frac{\sigma_C^2}{[C]_{sm}^2} = \frac{\sigma_{\Delta t_{sm}}^2}{\Delta t_{sm}^2} + \frac{\sigma_{\Delta t_{cl}}^2}{\Delta t_{cl}^2} \tag{121}$$

and the relative square error of the time difference is given by Equation (122):

$$\frac{\sigma_{\Delta t}^2}{\Delta t^2} = 2\frac{\sigma_t^2}{\Delta t^2} + \frac{\sigma_S^2}{k^2\Delta t^2}\quad\frac{1}{(S_\infty - S_1)^2} + \frac{1}{(S_\infty - S_2)^2} \tag{122}$$

In this case, the error depends on two opposite factors, the reduction of uncertainty when Δt increases, and the lack of precision in the time measurement when S_2 nears S_∞. A graphical inspection of Equation (122) shows that precision increases as S_∞ increases, S_1 decreases, and S_2 takes a value around 0.7 times S_∞, at which Equation (122) has a minimum depending on σ_t^2, σ_S^2, and k values.

3.3 Multicomponent Methods

Kinetic methods based on the different rates at which the components of a mixture react with a common reagent can be used to determine several analytes simultaneously.[23] However, kinetic-based multicomponent determinations have found fewer applications than those devoted to the determination of only one species. This reflects the fact that conditions for determining more than one species simultaneously, and suitable multicomponent reactions, are difficult to find.

3.3.1 Differential Methods

Several strategies have been employed[24] in the simultaneous determination of two or more species. For two analytes, one of the most popular approaches has been the

logarithmic extrapolation method, because of its simplicity and its greater accuracy than other methods when the ratio of the rate constants is large. This method assumes that the signal is due to the slowest-reacting component, A, after reacting to completion the faster component, B. Equation (123) gives:

$$\ln(S_\infty - S) \cong -k_A t + \ln(s[A]_0) \tag{123}$$

Thus, fitting the final data points, the concentration of the slowest component could be obtained. The faster component concentration can be evaluated from the difference between the final and the initial signal. Better results are obtained if weights, $w_i = (S_\infty - S_i)^2$, are used[2] to compensate the logarithmic transformation. The systematic error of the method depends on the ratio of the rate constants, the extent of the reactions, and the uncertainty in the final signal value. Figure 6 shows that the error decreases as the extent of the faster reaction increases and the extent of the slower reaction decreases. On the other hand, the systematic errors in the final signal can produce dramatic effects on the results. From Equation (123) and supposing that the value of k_A is known, the error yields by the extrapolation from one data point, S, will be given by Equation (124):

$$\frac{\varepsilon_A}{[A]_0} = \frac{\varepsilon_{S_\infty}}{S_\infty - S} \tag{124}$$

Figure 6 Relative error in the determination of the slower species of a binary mixture using the logarithmic extrapolation method, as a function of the extents of reaction at the first experimental point taken for the extrapolation.

The overall process leads to an error that will be a function of a combination of terms like Equation (124) for all the points used. For this reason, to reduce the effect of the propagation of a systematic error in S_∞, the points must be taken as near the origin as the reaction rates ratio permits.

Another widely used approach is the method of proportional equations, which involves the resolution of a system of simultaneous equations to obtain analyte concentrations. For two substances, Equation (125) relates the signal value to the analyte concentration:

$$\begin{aligned} S - S_0 &= s_A[A]_0(1 - e^{-k_A t}) + s_B[B]_0(1 - e^{-k_B t}) \\ &= \Psi_A[A]_0 + \Psi_B[B]_0 \end{aligned} \tag{125}$$

The above expression indicates that the analyte concentrations can be obtained by solving a system of linear equations when the signal is measured at two different times. This method does not require a prior knowledge of S_∞, but the proportionality factors, Ψ, must be carefully evaluated at each time from pure solutions of A and B separately. Although the knowledge of s and k values should permit theoretical calculations of Ψ, the empirical evaluation is preferred to minimize the effect of experimental variables. The solutions of the system for two species is given by Equation (126):

$$[A]_0 = \frac{\Psi_{2B}S_1 - \Psi_{1B}S_2}{D} \quad [B]_0 = \frac{\Psi_{1A}S_2 - \Psi_{2A}S_1}{D} \tag{126}$$

where the S values have been corrected with regard to the initial signal, and $D = \Psi_{1A}\Psi_{2B} - \Psi_{2A}\Psi_{1B}$ is the determinant of the $\boldsymbol{\Psi}$ matrix.

The study of the effect of experimental errors on the evaluated concentrations will be based on the hypothesis that errors affect the measured signals due to the uncertainties in time, signal measurement, experimental conditions, and so on. The error in calibration will affect the proportionality constants; for instance, the error in Ψ_{1A} is given by Equation (127):

$$\Psi_{1A} = \frac{S^0_{1A} + \varepsilon_{1A}}{[A]_{cl}} = \Psi^0_{1A} + \frac{\varepsilon_{1A}}{[A]_{cl}} \tag{127}$$

where $[A]_{cl}$ is the concentration of A species in the calibration. By introducing all the measurement errors in Equation (126), expressions for the error concentrations are given by Equations (128) and (129):

$$\varepsilon_A \cong \frac{\begin{aligned}&\Psi_{1B}\left(\frac{[B]_{sm}}{[B]_{cl}}\varepsilon_{2B} + \frac{[A]_{sm}}{[A]_{cl}}\varepsilon_{2A} - \varepsilon_2\right) \\ &-\Psi_{2B}\left(\frac{[B]_{sm}}{[B]_{cl}}\varepsilon_{1B} + \frac{[A]_{sm}}{[A]_{cl}}\varepsilon_{1A} - \varepsilon_1\right)\end{aligned}}{D} \tag{128}$$

$$\varepsilon_B \cong \frac{\Psi_{2A}\left(\frac{[B]_{sm}}{[B]_{cl}}\varepsilon_{1B} + \frac{[A]_{sm}}{[A]_{cl}}\varepsilon_{1A} - \varepsilon_1\right) - \Psi_{1A}\left(\frac{[B]_{sm}}{[B]_{cl}}\varepsilon_{2B} + \frac{[A]_{sm}}{[A]_{cl}}\varepsilon_{2A} - \varepsilon_2\right)}{D} \quad (129)$$

These equations indicate that the concentration errors depend on: the value of the uncertainty in the measurements; the value of the proportionality constants, and thus on the experimental design; and the relationship between the concentrations in the calibration and the sample. Besides, the systematic errors can be partially compensated when they are in the same kinetic curve or reinforced when they are at the same time in the calibration curves. On the other hand, the systematic errors affect each substance in an opposite way, that is, when the error of A is positive the error of B will be negative and vice versa. Finally, errors in the first experimental point will have a larger effect because the proportionality constants of the second calibration time, Ψ_{2A} and Ψ_{2B}, are higher than those of the first calibration time, Ψ_{1A} and Ψ_{1B}.

The optimal experimental design will be the one that makes the determinant D the maximum. Equation (130) gives:

$$D = s_A s_B \left(1 - e^{-k_A t_1}\right)\left(1 - e^{-k_B t_2}\right) - \left(1 - e^{-k_A t_2}\right)\left(1 - e^{-k_B t_1}\right) \quad (130)$$

This determinant is maximum when t_2 is the highest possible, and t_1 is given by Equation (131):

$$t_1 = \frac{\ln[(k_B/k_A)(1 - e^{-k_A t_2})/(1 - e^{-k_B t_2})]}{k_B - k_A} \quad (131)$$

A drawback of proportional equations is that although a fairly large number of data points is obtained, only a small fraction, two in a binary mixture, are used in the computation, thereby limiting precision. On the other hand, although theoretically there is no limitation on the number of components that could be determined, a practical limit only allows the resolution of mixtures of up to four components with acceptable errors, as long as their rate constants are sufficiently different. The high propagation of experimental errors, as shown in Equations (128) and (129), imposes the restriction. However, this method provides better precision and accuracy than other differential methods.[25]

3.3.2 Regression Methods

Experimental data can be condensed by fitting them to a model that depends on adjustable parameters. Generally, these parameters are the rate constants in the calibration step and the analyte concentrations during the determination procedure. An objective function must be chosen to measure the agreement between data and model response with regard to a particular set of parameter values. The fitting problem reduces to a minimization process that searches the set of parameter values that minimize the objective function. Finally, statistical tools are needed to measure the uncertainty of the determined parameters.

3.3.2.1 Least-squares Regression The least-squares fitting is a maximum likelihood estimation of the parameters, provided that the measurement errors are independent and normally distributed.[4] For a single response, the least-squares can be written as in Equation (132):

$$\chi = \sum_{i=1}^{N} w_i (Y_i - S_i)^2 = \sum_{i=1}^{N} w_i r_i^2 \quad (132)$$

where w_i is the weight assigned to the ith point, Y_i the experimental signal, S_i the signal value predicted by the model, and r_i the residual or difference between the experimental and predicted values.

Conventionally, the weight of an experimental point, w_i, has been taken as inversely proportional to its variance, σ_i, for uncorrelated measurements, as given by Equation (133):

$$w_i = \frac{1}{\sigma_i^2} \quad (133)$$

In this way, the more uncertain experimental data are considered less. Another kind of weight arises from the use of a transformed variable,[2] Z, from the raw experimental variable, Y. Equation (134) gives:

$$w_i = \frac{(1/\sigma_i^2)}{(dZ_i/dY_i)^2} \quad (134)$$

For instance, when a logarithmic transformation is performed the weights must be $w_i = (S_i/\sigma_i)^2$. It can be shown that the transformation causes a distortion in the informative structure of the data[26] and that weights given in Equation (134) restore the original structure.

The minimization of the least-squares function can be done using several methods.[27] The Newton–Raphson method is based on the Taylor's series expansion of the gradient, $\mathbf{G}$, as shown by Equation (135):

$$\mathbf{G}(\mathbf{P} + \Delta\mathbf{P}) = \mathbf{G}(\mathbf{P}) + \mathbf{H}(\mathbf{P})\Delta\mathbf{P} + \ldots \quad (135)$$

where $\mathbf{P}$ and $\Delta\mathbf{P}$ are the parameter and the parameter increment vectors, and $\mathbf{H}$ the Hessian matrix. By neglecting the higher-order terms and setting the gradient equal to zero, Equation (135) can be easily solved for the value of $\Delta\mathbf{P}$ that leads to the desired minimum as shown in Equation (136):

$$\Delta\mathbf{P} = -\mathbf{H}(\mathbf{P})^{-1}\mathbf{G}(\mathbf{P}) \quad (136)$$

In general, the higher-order terms in Equation (135) are not negligible, and hence an iterative procedure has to be used. In least-squares regression problems, the elements of gradient and Hessian are given by Equations (137) and (138):

$$g_i = \frac{\partial \chi}{\partial P_i} = -2\sum_{k=1}^{N} w_k \frac{\partial S_k}{\partial P_i} r_k \tag{137}$$

$$h_{ij} = \frac{\partial^2 \chi}{\partial P_i \partial P_j} \cong 2\sum_{k=1}^{N} w_k \frac{\partial S_k}{\partial P_i}\frac{\partial S_k}{\partial P_j} \tag{138}$$

where the second-order derivative terms, in the Hessian element, have been dismissed. Using this approximation in Equation (136) leads to the iterative expression shown in Equation (139):

$$\mathbf{P}_{n+1} = \mathbf{P}_n + (\mathbf{X}^{\mathrm{T}}\mathbf{W}\mathbf{X})^{-1}\mathbf{X}^{\mathrm{T}}\mathbf{W}\mathbf{r} \tag{139}$$

where $\mathbf{W}$ is the diagonal matrix of weights, $\mathbf{r}$ the residuals vector, $\mathbf{X}$ the Jacobian matrix ($x_{ij} = \partial S_i/\partial P_j$), and $\mathbf{X}^{\mathrm{T}}$ denotes the transpose of the matrix $\mathbf{X}$. This procedure is often called the Gauss–Newton method.

The least-squares function of a lineal model is quadratic and the minimum is reached in a single step. Then, taking the origin as the initial parameters vector, Equation (139) leads to Equation (140):

$$\mathbf{P}^* = (\mathbf{X}^{\mathrm{T}}\mathbf{W}\mathbf{X})^{-1}\mathbf{X}^{\mathrm{T}}\mathbf{W}\mathbf{Y} \tag{140}$$

where $\mathbf{P}^*$ is the optimum parameter vector.

An important part of the optimization process is to determine the uncertainty of the estimated parameters.[28] From the linearized model shown in Equation (136), the variance–covariance matrix, $\mathbf{C}$, that contains estimates of the errors in the parameters, is given by Equation (141):

$$\mathbf{C} = \frac{\chi^*}{N-n}\mathbf{H}^{-1} \tag{141}$$

where χ^* is the value of the least-squares objective function at the minimum, N the number of experimental points and n the number of fitted parameters. Thus, the estimated standard deviation in the ith parameter is given by Equation (142):

$$\sigma_{P_i} = \sqrt{C_{ii}} \tag{142}$$

It is important to realize that the Hessian matrix $\mathbf{H}$ is a curvature matrix of the least-squares objective function, and low curvatures around the optimum result in high uncertainties in the estimated parameters. The curvature decreases when the correlation of predictor variables (the columns of the $\mathbf{X}$ matrix) increases. In multicomponent analysis using kinetic data, the correlation could be high because the kinetic signals usually have similar profiles, leading to low curvatures and large uncertainties. Obviously, the problem increases when the rate constants become more similar.

3.3.2.2 Error Sensitivity Analysis in Least-squares Regression It is well known that the accuracy of a determination can be ruined by small systematic errors in the experimental conditions such as reagent concentration, time, temperature, or calibration parameters. To evaluate the influence of uncertainties in experimental variables, an error sensitivity analysis must be performed. The error sensitivity of the parameter P with respect to an error in the variable X can be obtained using Equation (143):[29]

$$\delta_{PX} = \frac{\mathrm{d}P^*}{\mathrm{d}X} = -\frac{h_{PX}}{h_{PP}} \tag{143}$$

where P^* is the optimized parameter, and h_{PX} and h_{PP} are the corresponding elements of the Hessian matrix. This equation gives the estimated error in the determination of P by least-squares regression, when the systematic error in the variable X equals unity. It must be noted that X can be any variable having an influence on the value of the experimental points, and an explicit relationship between X and P is not required. In this way, the relative systematic error in P owing to a relative error in X will given by Equation (144):

$$\varepsilon_{rP} = -\frac{h_{PX}}{h_{PP}}\frac{X}{P}\varepsilon_{r_X} \tag{144}$$

When several experimental variables are affected by errors, the propagation of systematic errors must be applied as in Equation (145):

$$\varepsilon_P = \delta_{PX_1}\varepsilon_{X_1} + \delta_{PX_2}\varepsilon_{X_2} \tag{145}$$

Finally, when several parameters are simultaneously fitted, the propagation of errors rule leads to a system of lineal equations. Equations (146) and (147) show that for two parameters and one variable we have:

$$\varepsilon_{P_1} = \delta_{P_1X}\varepsilon_X + \delta_{P_1P_2}\varepsilon_{P_2} \tag{146}$$

$$\varepsilon_{P_2} = \delta_{P_2X}\varepsilon_X + \delta_{P_2P_1}\varepsilon_{P_1} \tag{147}$$

The resolution of this system will yield the propagated errors in the parameters.

Table 5 shows the relative error sensitivities for the determination of the initial concentration and rate constant for a second-order reaction at several reagent concentrations. The rate constant, k, is more affected by systematic errors than the initial concentration. On the other hand, error propagation is, in general, lower when pseudo-first-order experimental conditions are used.

3.3.2.3 Principal Component Regression Least-squares regression techniques can be misused if care is not

Table 5 Relative error sensitivities for the determination of the initial concentration and the rate constant

	$[A]_0$			k		
	k	$[R]_0$	S_b	$[A]_0$	$[R]_0$	S_b
$[R]_0 = 1$	−0.35	−0.35	−0.64	−2.4	−1.0	−1.7
$[R]_0 = 0.1$	−0.34	−0.35	−0.65	−2.4	−1.1	−1.8
$[R]_0 = 0.011$	−0.26	−0.73	−0.88	−2.9	−2.3	−2.8

Experimental conditions were: $[A]_0 = 0.01$, $s = 100$, $k = 1$ and 120 experimental points were used taking 95% extent of reaction. Relative error in blank signal, S_b, was referred to $S_\infty/2$.

applied in ascertaining the suitability of the model for describing the data. On the other hand, the correlation between the kinetic behavior of the different substances limits the number of species that can be simultaneously determined. Principal component regression (PCR), partial least-squares (PLS) regression and KF regression are procedures that have been applied to obtain kinetic parameters from noisy data, with models that are not well fixed, and to reduce the effects of correlation.

A major drawback of multiple least-squares is derived from the increase of collinearity among the predictor variables (the columns of the **X** matrix). Collinearity arises from similar signal responses for some analytes, from badly conditioned experimental designs, or from an overdimensioned number of predictor variables. All these problems increase when a large number of independent variables are involved. In this case, the Hessian becomes nearly singular and the inversion leads to a large variance in the parameters, as shown in Equation (141). This is a common situation when applying kinetic methods, due to the similar behavior of time-dependent signals in multicomponent analysis. PCR copes with this problem by performing a dimensional reduction by a principal component analysis of **X**.

The principal component analysis involves the rotation of coordinate axes to orientate them in the direction that maximizes the empirical variance of the predictor variables.[30] The new axes are called eigenvectors or loadings, **V**, and the new predictor variables, principal components, scores, or factors **T**. These scores are not correlated and, thus, principal component analysis compresses **X** to its most relevant factors **T**. The matrix **X** must be mean column-centered, previously. The transformation is given by Equation (148):

$$\mathbf{X} = \mathbf{T}\mathbf{V}^{\mathrm{T}} + \mathbf{E} \tag{148}$$

where **E** is the matrix of residuals of **X** generated when the number of factors that account for the variability in **X** is less than the number of original predictor variables. Thereby, the common structures in **X** are compressed into a stabilized, more easily interpretable model, leaving out much of the noise as residuals. Eigenvector decomposition can be performed using several algorithms.[4,31] The nonlinear iterative partial least-squares (NIPALS) method[30] is a simple algorithm that extracts one factor at a time, employing an iterative procedure to obtain the loading and score vectors from the residual matrix, obtained after estimation of the previous factors. In a second step, the Y-variables are regressed on **T**. Since the principal components are uncorrelated, the regression can proceed factor by factor, choosing only the factors that involve real variability of the **X** matrix and rejecting those that only account for noise. The PCR estimate of the parameters, using the most relevant factors, can be written as Equation (149):

$$\mathbf{P}_{\mathrm{PCR}} = \mathbf{V}(\mathbf{T}^{\mathrm{T}}\mathbf{T})^{-1}\mathbf{T}^{\mathrm{T}}\mathbf{Y} \tag{149}$$

Since the scores in **T** are uncorrelated, Equation (150) gives:

$$\mathbf{T}^{\mathrm{T}}\mathbf{T} = \mathrm{diag}\left(\frac{1}{v_m}\right. \tag{150}$$

where v_m is the eigenvalue of the mth factor. The eigenvalues show how much variability each factor removes from **X**.

The main advantage of PCR is that it allows redundant factors and noise variability to be removed by performing a dimension reduction. However, an important problem is how to define the number of relevant factors. A good calibration practice is to extract more factors than are expected to be needed, and afterwards eliminate those that appear to be irrelevant or unreliable. Finally, it is important to realize that PCR coincides with multivariate least-squares regression when all factors are used.

3.3.2.4 Partial Least-squares Regression This method differs from PCR by including the dependent variable in the data compression and decomposition operations; this makes the method more complex as two loading vectors are required to provide orthogonality of the factors. The factors, called latent variables, are chosen in order to use **X** and **Y** efficiently, and provide a strong fit between them. In this way, the PLS factors can be seen as modified principal components improving the correlation. In the PLS algorithm, two principal component analyses are carried out, one for **X** and another for **Y**, by applying NIPALS to the column-centered matrices **X** and **Y** as shown in Equations (151) and (152):

$$\mathbf{X} = \mathbf{T}\mathbf{V}^{\mathrm{T}} + \mathbf{E} \tag{151}$$

$$\mathbf{Y} = \mathbf{U}\mathbf{B}^{\mathrm{T}} + \mathbf{F} \tag{152}$$

where **V** and **B** are the loading matrices and **T** and **U** the score matrices for **X** and **Y**, respectively. A linear

relationship as shown in Equation (153) between latent variables is set to enhance the correlation between the predictors and the response:

$$\mathbf{U} = \mathbf{TQ} + \mathbf{D} \tag{153}$$

where **Q** is a diagonal matrix that accounts for the correlation between latent variables, and **D** is the residuals matrix. Equation (154) relates **T** to **Y**:

$$\mathbf{Y} = \mathbf{TC}^{\mathrm{T}} + \mathbf{F} \tag{154}$$

Finally, the estimated parameters can be obtained by using the expression in Equation (155):

$$\mathbf{P} = \mathbf{W}(\mathbf{V}^{\mathrm{T}}\mathbf{W})^{-1}\mathbf{C}^{\mathrm{T}} \tag{155}$$

where **W** is the matrix of **X**-factor weights that correlate each **u** vector with **X** residuals. Equation (156) gives:

$$\mathbf{w}_j = c\mathbf{E}_j^{\mathrm{T}}\mathbf{u}_j \tag{156}$$

where c is the scaling constant that makes the length of the final $\mathbf{w}_j$ vector equal to 1, and $\mathbf{E}_{\mathrm{j}}$ is obtained from Equation (157):

$$\mathbf{E}_j = \mathbf{X} - \sum_{i=1}^{j-1} \mathbf{t}_i\mathbf{p}_i^{\mathrm{T}} \tag{157}$$

and at the beginning $\mathbf{E}_1 = \mathbf{X}$.

When all factors are used, the PLS predictor is equal to the least-squares predictor. PLS and PCA are the so-called soft-modeling methods in which an empirical model is derived from the data. The model is built up from a number of calibration samples. The use of these methods in kinetic problems[32] is growing due to their efficiency in dealing with problems from incomplete models, imprecise data sets, and interactions among the components.

3.3.2.5 Kalman Filter The KF is a recursive algorithm that introduces a new experimental point at each calculation step, and optimizes the point residual and the mean error of the estimates of the parameters (state variables). The linear KF requires the model to be linear with respect to the state variables, and has been used for pseudo-first-order kinetic determinations.[33] In this algorithm, as in linear least-squares, the rate constants must be well-known and are supposed to be invariant from run to run. This assumption is a serious drawback that affects the results, since the pseudo-first-order rate constants are functions of many experimental factors (temperature, pH, ionic strength, and so on).

The extended KF must be used with nonlinear models. This algorithm is based on a linear term truncated Taylor's series expansion about the current estimate of the parameters. The extended KF is a statistically nonoptimal procedure, and more prone to the influence of the initial guesses of the parameters than the linear form, due to the inherent error caused by truncation of higher-order terms. Rate constants can be included among the parameters to be estimated and adjusted in the process of the filter, as in the NLS method. Both the least-squares and the KF algorithms are model-based, or hard-modeling methods, in which accurate model information is indispensable to obtain good results.

The extended Kalman algorithm for time-invariant parameters can be set out in the following steps:

1. Initialize $\mathbf{P}(0)$ and $\mathbf{x}(0)$, **P** being the error covariance matrix, related to the inverse of the Hessian in least-squares, and **x** the vector of the parameters to be estimated. It is recommended to choose for $\mathbf{P}(0)$ a diagonal matrix with very large diagonal elements, expressing the large uncertainty in the chosen starting values of $\mathbf{x}(0)$.
2. Compute the linearized measurement function vector, $\mathbf{h}(j)$, that coincides with the jth row of the Jacobian matrix as shown in Equation (158):

$$\mathbf{h}(j)_k = \frac{\partial S[\mathbf{x}(j-1)]_j}{\partial x_k} \tag{158}$$

   where S is the model estimated signal.
3. Update the Kalman gain vector, $\mathbf{k}(j)$, and the error covariance matrix using Equations (159) and (160):

$$\mathbf{k}(j) = \frac{\mathbf{P}(j-1)\mathbf{h}(j)}{\mathbf{h}^{\mathrm{T}}(j)\mathbf{P}(j-1)\mathbf{h}(j) + V(j)} \tag{159}$$

$$\mathbf{P}(j) = \mathbf{P}(j-1) - \mathbf{k}(j)[\mathbf{h}^{\mathrm{T}}(j)\mathbf{P}(j-1)] \tag{160}$$

   where $V(j)$ is the variance of the jth experimental point. The Kalman gain vector is chosen to be the gain or blending factor that minimizes the a posteriori error covariance matrix $\mathbf{P}(j)$.[34]
4. Predict the value of the signal at point j, $S(j)$, with the parameters obtained in the $j-1$ cycle, and evaluate the residual or innovation, $I(j)$, using Equation (161):

$$I(j) = Y(j) - S[\mathbf{x}(j-1)]_j \tag{161}$$

5. Update the predicted parameters using Equation (162):

$$\mathbf{x}(j) = \mathbf{x}(j-1) + \mathbf{k}(j)I(j) \tag{162}$$

6. Return to step 2, until all experimental points have been included.

When the parameters to be estimated are not constant but vary with time, a dynamic KF can be used in which a new step must be included between steps 5 and 6.

Table 6 Average absolute relative errors of the estimated concentrations of two binary mixtures using spectral-kinetic data and different algorithms of data treatment[a]

No. of wavelengths:	*m*-ABA/*p*-ABA[b]			*o*-ABA/*m*-ABA		
	1	6	41	1	6	36
NLS[c]	–[d]	56/20	61/7.8	–[d]	–[d]	–[d]
Linear Kalman	2.7/2.9	2.9/5.4	3.4/4.6	23/23	14/13	8.0/9.1
Extended Kalman	8.3/4.6	4.0/3.8	3.5/3.6	21/25	4.1/3.3	2.4/3.3
PLS	2.6/1.8	2.6/1.7	2.8/1.9	13/17	2.8/2.8	2.5/2.7

[a] From Xie et al.[35]
[b] ABA, aminobenzoic acid. Coupling reaction of diazotized sulfanilamide with the *o*-, *m*- and *p*-ABAs. The pseudo-first-order rate constants for the reactions performed at pH = 3.9 were $k_o = 4.67$, $k_m = 9.24$, and $k_p = 1.45$; these values are highly affected by pH variations.
[c] NLS regression using the Powell algorithm.[27]
[d] Extremely large absurd values.

5′. Extrapolate the parameters vector and the error covariance matrix using Equations (163) and (164):

$$\mathbf{x}(j+1|j) = \mathbf{F}(j+1, j)\mathbf{x}(j|j) + \mathbf{w}(j) \quad (163)$$

$$\mathbf{P}(j+1|j) = \mathbf{F}(j+1, j)\mathbf{P}(j|j)\mathbf{F}^{\mathrm{T}}(j+1, j) + \mathbf{Q}(j) \quad (164)$$

where the matrix $\mathbf{F}(j+1, j)$ is the system transition matrix, which describes how the system state changes from time t_j to t_{j+1}. The vector $\mathbf{w}(j)$ consists of the noise contribution to each of the parameters, and $\mathbf{Q}(j)$ is the variance–covariance matrix of the system noise which contains the variance of $\mathbf{w}$.

In line with KF literature, in the above description the common notation has been used in spite of the difference with the notation in other multivariate methods. The results of the KF depend on the initial estimates of the parameters. On the other hand, they rely on the initial guesses for the variance of the corresponding estimated values, and on the variance of the measurement noise.

Table 6 shows the average absolute relative error produced in the simultaneous determination of two substances using spectral-kinetic data, and different regression methods with three different numbers of wavelengths.[35] For the NLS the estimated error was extremely large for some of the mixtures. On the other hand, PLS and extended KF gave satisfactory results if the difference of the rate constants was large enough (*m*-ABA/*p*-ABA mixture). However, for closer rate constants (*o*-ABA/*m*-ABA mixture), a larger number of wavelengths must be used to improve the results. It can be deduced that PLS gave better results than the KFs, and that the extended KF performed better than the linear one for these experimental data. Besides, the more wavelengths used, the less the influence of the errors on the rate constants. Moreover, the influence of the number of wavelengths on the extended KF was not so significant as in the linear KF, which was attributed to the correction of the rate constants.

ABBREVIATIONS AND ACRONYMS

ABA	Aminobenzoic Acid
KF	Kalman Filter
KMS	Kezky–Mangerlsdorf–Swinbourne
NIPALS	Nonlinear Iterative Partial Least-squares
NLS	Nonlinear Least-squares
o.d.e.	Ordinary Differential Equation
PCR	Principal Component Regression
PK	Predictive Kinetic
PLS	Partial Least-squares

Kinetic differential rate determinations are a measurement approach in kinetic methods of analysis where two or more components are determinated based on the different rates at which they interact with a common reagent.

1 INTRODUCTION

Multicomponent analysis is one of the main goals of the modern analytical chemistry. The simultaneous or sequential determination of several analytes in the same sample can be accomplished without or with physical separation in space (e.g. in chromatographic techniques). Multicomponent kinetic determinations, traditionally called ''differential reaction rate methods'', are based on the different rate at which two on more species in solution react with a common reagent.[1] They allow the variation of the analytical signal yielded by each species to be ''separated'' on a different timescale, thereby avoiding the need to separate the components physically. Separation techniques are usually time-consuming and may result in sample loss and contamination. Hence differential rate methods are of great interest in the context of kinetic methods of analysis as they are effective alternatives to multicomponent analysis, especially when only a few components in a mixture are to be determined. The principles and features of differential rate methods have been compiled in two books on kinetic methods[2,3] and also in several reviews on the topic.[4,5]

Classical differential rate methods, developed in the 1960s–1970s, were based on simple mathematical equations and required only a few kinetic data for application. They were only applied to first- or pseudo-first-order reactions in order to resolve binary mixtures with a rate constant ratio above about three. Modern differential rate methods combine rate discrimination with mathematical and/or spectral/instrumental discrimination to provide much better performance and a wider scope of application by virtue of their using much greater amounts of information. The development of new computerized data processing methods has been the key to both the implementation of variably complex mathematical algorithms (kinetometric approaches) and the handling of multidimensional data such as the multiwavelength readings provided by diode array spectrophotometers. These methods have expanded the scope of conventional reaction rate methods to reaction orders higher than first- or pseudo-first order, rate constant ratios near unity and even mixtures exhibiting mutual kinetic effects (synergism). As the efficiency of mathematical discrimination and/or spectral discrimination increases, the need for kinetic discrimination (based on the difference between

reaction rates) is reduced, so much so that a system with completely overlapped kinetics can be effectively resolved provided that some spectral difference exists at the wavelength considered. These methods thus afford the kinetic resolution of mixtures of analytes on the basis of spectral differences rather than kinetic differences; as a result, the designation ''multicomponent kinetic methods'' is more appropriate than differential reaction rate methods. Finally, rate discrimination can also be combined with the physicochemical discrimination provided by micellar systems.

The potential of these modern methods can only be fully exploited for analytical purposes by using automated methods, which provide results of increment quality and enable multicomponent determinations in routine analyses. Various automated approaches (continuous and stopped-flow (SF) included) according to the way sample and reactants are mixed are possible. Their performance in terms of mixing expeditiousness and homogeneity depends on the rates of the reactions involved, especially with fast reactions (viz. with lifetimes of a few milliseconds or shorter).

This article describes currently available methods for kinetic multicomponents analysis that provide high-quality results and encompass a wide range of analytes in mixtures and analyte concentration ratios when used in combination with an automated method suitable for routine analyses.

2 THEORETICAL AND METHODOLOGICAL BACKGROUND

2.1 General Considerations

Differential kinetic methods have traditionally focussed on mixtures of components reacting at slightly or strongly different rates; however, methods for mixtures exhibiting small rate differences account for the majority of the work in this field. The analytical applicability of these methods is dependent on the relative values of the rate constants and on the ratio between the concentrations of the mixture components.

Let A and B be two substances in a mixture that react with a reagent R to yield two products (P and P′) which, though different in nature, are essentially similar with regard to the analytical property to be measured, according to the reactions shown here (Equations 1 and 2):

$$A + R \xrightarrow{k_A} P \quad (1)$$

$$B + R \xrightarrow{k_B} P' \quad (2)$$

where k_A and k_B are the rate constants for reaction of A and B, respectively, which are first-order with respect to each mixture components (i.e. $[R]_0 \gg [A]_0$ and $[R]_0 \gg [B]_0$).

If the mixture to be resolved exhibits a large difference between the reaction rates (i.e. k_A/k_B is sufficiently different from unity), then the analysis is quite simple because each species can be treated separately. In this case, one can assume that, over any time interval, only one species will react since the other either will have already reacted completely or be reacting so slowly that it could hardly interfere with the reaction of interest.

If $k_A > k_B$ but B reacts to an appreciable extent over a given time interval, then the ratio of their rate constants, k_A/k_B, needed to obtain a given error in the concentration of A can be determined from the ratio of the respective first-order rate integrated equations for both components (Equations 3 and 4):

$$\ln\left(\frac{[A]_0}{[A]_t}\right) = k_A t; \quad \ln\left(\frac{[B]_0}{[B]_t}\right) = k_B t \quad (3)$$

i.e.

$$\frac{\ln([A]_0/[A]_t)}{\ln([B]_0/[B]_t)} = \frac{k_A}{k_B} \quad (4)$$

This equation is time-dependent and relates the extent of both reactions to their rate constants. If a maximum error of 1% is considered to be acceptable (i.e. if there is still 1% of A present when less than 1% of B has reacted) then the k_A/k_B ratio in Equation (4) should be at least 463. In practice, a minimum ratio of 500 is commonly adopted.

As the ratio of the two rate constants, k_A/k_B, approaches unity, the errors in the estimated concentrations of the components in the mixture become larger. Hence, traditional methods for small rate differences involve the selective determination of the more rapidly reacting species, either by altering the kinetics of a system via appropriate changes in the reaction conditions (e.g. temperature, solvent, reactant concentrations) or by masking the species with a suitable inhibitor. The concentration of the second species can be obtained by a similar approach or by the difference from a determination of the sum of the two concentrations. However, the most frequently used methods for the simultaneous determination of species with small differences in their rate constants are based on mathematical approaches for systems having unalterable rate constants (such constants often can not be separated to a sufficient degree by either of the above-described types of method). The most popular approaches to differential rate determinations

historically have been logarithmic extrapolation methods and the method of proportional equations (classical methods).[2]

These methods are available for various reaction orders[2] of which the pseudo-first is the most widely considered. They assume the simultaneous contribution of the two-reaction component to the analytical signal according to Equations (1) and (2). If the pseudo-first order reaction rates of two substances are different and independent of each other (i.e. if no mutual kinetic effects are present), then the sum of the contribution of A and B at time t, C_t, is given by Equation (5)

$$C_t = [\mathrm{A}]_t + [\mathrm{B}]_t = [\mathrm{P}]_\infty - [\mathrm{P}]_t = [\mathrm{A}]_0 \exp(-k_\mathrm{A} t) + [\mathrm{B}]_0 \exp(-k_\mathrm{B} t) \qquad (5)$$

where $[\mathrm{A}]_t$ and $[\mathrm{B}]_t$ are obtained, respectively, from the exponential forms of the integrated rate equations (Equation 3). $[\mathrm{P}]_\infty$ is the maximum total product concentration, which is usually measured after allowing the reaction to proceed for a sufficiently long time and is in itself a measure of the total initial concentration of reactants, $[\mathrm{A}]_0 + [\mathrm{B}]_0$, [P] can be replaced with a measurable property proportional to the product concentration such as the absorbance, fluorescence or chemiluminescence intensity, or potential. Equation (5) is the basis for application of classical and some kinetometric methods.

3 KINETIC DISCRIMINATION: CLASSICAL METHODS

3.1 Logarithmic Extrapolation and Proportional Equations

The *logarithmic extrapolation method* is the most commonly used graphical linear method for the simultaneous kinetic determination of species. The method is based on Equation (5) and uses plots of $\log C_t$ or $\log[(\mathrm{P})_\infty - (\mathrm{P})_t]$ as a function of time (Figure 1). The result is a curve unless $k_\mathrm{A} = k_\mathrm{B}$, in which case a straight line is obtained. If species A disappears at a higher rate than B (i.e. if $k_\mathrm{A} > k_\mathrm{B}$), then $[\mathrm{A}]_t \to 0$ and the curve eventually becomes a line (Figure 1), Equation (6)

$$\log C_t = \log([\mathrm{P}]_\infty - [\mathrm{P}]_t) = \log [\mathrm{B}]_0 - \frac{k_\mathrm{B} t}{2.303} \qquad (6)$$

The intercept of the curve provides the initial concentration of B, $[\mathrm{B}]_0$, that of the other component, $[\mathrm{A}]_0$, being obtained by difference once $[\mathrm{A}]_0 + [\mathrm{B}]_0$ has been determined from $[\mathrm{P}]_\infty$. If a photometric detection technique is applied, then Equation (6) can be written as Equation (7):

$$\log(D_\infty - D_t) = \log \varepsilon_\mathrm{B}[\mathrm{B}]_0 - \frac{k_\mathrm{B} t}{2.303} \qquad (7)$$

Figure 1 Logarithmic extrapolation method for first-order reactions.

where D_∞ and D_t are the absorbances measured after the reaction has developed to completion and after a time t near the start of the linear region, and ε_B is the molar absorptivity of B (known beforehand).

This method features several advantages, namely: (1) no prior knowledge of the rate constant of A or B is necessary; (2) it is less prone to error as the linear plot is constructed from several points; (3) it can be applied to ternary mixtures provided the rate constants of the three components are sufficiently different (even in the presence of synergistic effects) as it is not limited to pseudo-first-order reactions; (4) rate constant ratios as low as five are acceptable under certain conditions (e.g. with favorable concentration ratios and if somewhat large errors are acceptable). However, at least 99% of the more reactive species should be consumed in the process if valid data are to be obtained and the total initial concentration of all the species involved should be known for the method to be applicable. In addition, the method is somewhat laborious as it entails the continuous recording of the measured property and obtaining the required $[\mathrm{P}]_\infty - [\mathrm{P}]_t$ values from the resulting curve. For two reactions following second-order kinetics in which $[\mathrm{R}]_0 \approx [\mathrm{A}]_0 + [\mathrm{B}]_0$, the reaction rate can be expressed by Equation (8)

$$\frac{-\mathrm{d}[\mathrm{R}]}{\mathrm{d}t} = \frac{\mathrm{d}x}{\mathrm{d}t} = k_\mathrm{A}[\mathrm{R}]_t[\mathrm{A}]_t + k_\mathrm{B}[\mathrm{R}]_t[\mathrm{B}]_t \qquad (8)$$

where x is the amount of R consumed at any time t. If A reacts faster than B, then, when the [A] has reacted essentially to completion, Equation (8), after integration, gives Equation (9)

$$x = k_\mathrm{A}[\mathrm{B}]_t([\mathrm{R}]_0 - x)t + [\mathrm{A}]_0 \qquad (9)$$

$[\mathrm{A}]_0$ is then determined from the extrapolated intercept at $t = 0$ of a plot of x versus $[(\mathrm{R})_0 - x]t$.

The *proportional equation method* is a mathematical approach of wide use for the resolution of mixtures of closely related species; it is usually less time-consuming

than the previous method (especially if a microcomputer is used) and in the most cases requires no prior knowledge of the total concentrations of the mixture component. A rate constant ratio of four is usually acceptable and the ease with which the method can be automated make it suitable for fast reactions. However, it cannot be applied to processes subject to synergistic effects because the measured property must be additive in nature. On the other hand, the rate constants must be carefully calculated; if the reaction involves complex kinetics, then the applicability of the method relies on the accurate calculation of the different proportionality constants.

The practical procedure for pseudo-first rate reactions entails measuring C_t at two or more reaction times and formulating two Equations (10) and (11) similar to Equation (5):

$$[P]_\infty - [P]_{t_1} = [A]_0 \exp(-k_A t_1) + [B]_0 \exp(-k_B t_1) \quad (10)$$

$$[P]_\infty - [P]_{t_2} = [A]_0 \exp(-k_A t_2) + [B]_0 \exp(-k_B t_2) \quad (11)$$

the resolution of which provides the initial concentrations of the different components as functions of their respective rate constants (known beforehand).

Not only time, but any other experimental variable such as temperature or one related to the solvent or the physicochemical characteristics of the reactants can be used to formulate the simultaneous equations from which the required concentrations are to be calculated. Thus, the general equations for a binary mixture will be of the form (Equations 12 and 13)

$$f_1 = k_{A,1}[A]_0 + k_{B,1}[B]_0 \quad (12)$$

$$f_2 = k_{A,2}[A]_0 + k_{B,2}[B]_0 \quad (13)$$

where f is any measurable parameter determined under two different sets of conditions, and $k_{A,1}$ and $k_{A,2}$ are empirical or proportionality constants obtained separately for component A under different conditions in the same way as $k_{B,1}$ and $k_{B,2}$ are obtained for component B. Although any experimental variable is usable provided $k_{A,1}k_{B,2} \neq k_{A,2}k_{B,1}$, the optimum results are obtained with $k_{A,1}/k_{B,1} > 1$ for one set of conditions and $k_{A,2}/k_{B,2} < 1$ for the other.

Applications of these classical methods, most of which involve the resolution of binary mixtures of metal ions, have been compiled.[5]

3.2 Synergism

Both classical differential reaction-rate methods and new approaches rely on the assumption that the reaction rates of the species in the mixture are independent of each other. When this is not so, the mixture is said to be subject to a mutual kinetic or synergistic effect. Although synergism is not a frequent phenomenon, it is the chief source of error in differential kinetic analysis and should therefore be duly studied and controlled to ensure the accurate resolution of mixtures. Only the second-order logarithmic extrapolation and the Connors graphical extrapolation methods[2] are applicable in this event; in fact, if the cause of synergism is known, the reaction conditions are usually modified to avoid it.

Several approaches to the simultaneous resolution of mixtures subject to synergism have been reported. One is based on the Connors graphical interpolation method and involves using equations that can be formulated on the basis of any experimental parameter provided it is proportional to the concentration of the species concerned.[6] The method involves matching the concentration–time profile of a simple mixture to that of a reference mixture so that the initial concentrations of sample and reference are identical. Consider a mixture of two components, A and B, which react under pseudo-first order conditions with a reagent R to yield the same product, P. First, the concentration of P is measured as a function of time ($[P]_t^s$). Next, reference mixtures are reacted under the same conditions and $[P]_t^r$ is measured as a function of time. Once the concentration–time profiles for the sample and reference have been fully matched throughout the time range, $[P]_t^s = [P]_t^r$ and hence $[A]_0^r = [A]_0^s$ and $[B]_t^r = [B]_t^s$.

In practice, the calculation of $[A]_0^s$ involves the construction of several calibration graphs from plots of the final absorbance of component B in the presence of different known amounts of A. The intercepts of these plots are dependent on the concentration of component A. The concentration of B is calculated from the plots of the difference in the initial rates (IR) of the concentration–time curves for the sample and several reference solutions, viz. $(IR)^s - (IR)^r$ versus [B]. The method is also useful at low rate-constant ratios, which often pose problems in differential rate analyses. Its performance was evaluated with fast direct complex-formation reactions between cobalt and nickel and pyridoxal thiosemicarbazone (PTSC), which were subject to a synergistic effect, using a customized SF mixing module. The rate constant ratio was $k_{Ni}/k_{Co} = 2.63$. The determination of nickel in real samples entailed the prior determination of their cobalt content by applying the above-described procedure for calculation of $[A]_0^s$. Once this concentration had been evaluated, different known amounts of nickel in the range 1.0–5.0 $\mu g\,mL^{-1}$ were added to a sample aliquot containing a known cobalt concentration between 1.0–2.5 $\mu g\,mL^{-1}$, and reacted with PTSC.

4 MATHEMATICAL DISCRIMINATION: KINETOMETRIC METHODS

As noted in section 3, classical differential kinetic methods are based on simple mathematical equations and require only a few data points and rate constant ratios higher than about four for binary mixtures. The inception of digital computers has facilitated the use of multipoint methods that provide more information by exploiting the whole kinetic curve. This trend has materialized in the application of mathematical algorithms based on specific kinetic models[7] which allow the concentrations of two or more analytes in mixtures to be determined, whether or not the rate constants and reactions order involved are known beforehand, and for k_A/k_B ratios closer to unity.

Kinetometrics is a concept of increasing interest[8] as a result of dynamic systems frequently exhibiting a nonlinear relationship that can readily be modeled with computational aids. Curve fitting and related algorithms have proved useful in simultaneous kinetic determinations. In this section, the usefulness of recent kinetometric approaches such as Kalman filtering and artificial neural networks (ANN) is also discussed.

4.1 Multipoint Curve-fitting Methods

Curve-fitting methods compute values of parameters that represent the best fit of some mathematical model to signal–time data. Although curve fitting methods excel over direct computation methods (classical methods) for processing linear responses (pseudo-zero-order processes), they are also especially suitable for nonlinear responses.[7] Fits to nonlinear responses can be used to predict or extrapolate data obtained in another time region of the process.

In multipoint curve-fitting methods for kinetic analysis of mixtures[9,10] signal–time data pairs collected over a fixed period (7–8 half-lives of the slowest reacting component) are fitted to a mathematical model descriptive of the kinetic behavior of the mixture. The model frequently involves monitoring two or three pseudo-first-order reactions simultaneously through absorbance changes. The absorbance estimates as $D_\infty - D_0$ (D_∞ and D_0 being the absorbances at infinite and zero time, respectively) for each component, which result in the best least-squares fit to the experimental model, are used to compute the concentration of each component. This requires a prior knowledge of the pseudo-first-order rate constant of each component and the absorptivity of its product; also, no mutual kinetic effect should be present. This approach also affords satisfactory results from data processed over two half-lives of the slower reacting component by using nonlinear and multiple linear curve-fitting methods that yield virtually identical results.

Other reported methodologies for the resolution of mixtures of species include a new algorithm developed by Schechter[11] to resolve binary mixtures which requires no prior knowledge of the reaction orders or rate constants of the species involved and was tested on simulated data only. In addition, it allows the concentrations of the mixture components to be determined over broad ranges and the corresponding rate constants and reaction orders to be calculated. The algorithm, however, is somewhat less precise with reaction orders of exactly unity.

4.2 Kalman Filtering

Kalman filtering is an alternative curve-fitting approach that is gaining increasing interest in various fields of analytical chemistry and can be used to compute analyte concentrations or activities in enzymatic reactions. It is one of the most powerful algorithms available today for the simultaneous kinetic determination of species in mixtures (it is only surpassed by the neural network approach). Although it can be applied to single-component systems in order to calculate the initial concentration of the analyte and its first-order rate constant, its main applications are the correction of errors associated with between-run variations and, especially, simultaneous kinetic determinations. Thanks to its recursive nature, determinations can be performed in real time (thereby expediting the process) provided half lives allow it. It has proved useful for fitting linear and nonlinear (extended Kalman filter) kinetic data, depending on whether or not the rate constants of the two reactions are known beforehand (although the results are better when they are).

When the algorithm is used in its nonlinear form, its performance relies heavily on the initial parameter chosen and the number of iterations performed. Figure 2 illustrates how the Kalman filter can be used in multicomponent kinetic analysis. It is based on the rate equation for a binary mixture (Equation 5), which, taking into account that $[P]_t = [A]_0 - [A]_t + [B]_0 - [B]_t$ and that $[P]_t$ is replaced with the total absorbance at time t, D_t, can be expressed by Equation (14)

$$D_t = D_A[1 - \exp(-k_A t)] + D_B[1 - \exp(k_B t)] + C \quad (14)$$

where D_A and D_B and k_A and k_B are the net absorbance change and the pseudo-first-order rate constants for the two components, respectively, and C is the contribution of the background absorbance.

Investigations have shown this algorithm to be superior to classical multicomponent kinetic methods such as those of logarithmic extrapolation, single point and proportional equations in many respects, especially with regard to the affordable rate constant ratios of reactions for a binary mixture, which can be closer to unity than in the above-mentioned classical methods. Such is the case with

the resolution of mixtures of cortisone and hydrocortisone by reaction with Tetrazolium Blue, the rate constant ratio of which is 1.8; the results compared favorably with those of classical methods[12] (Table 1). Other mixtures of interest have also been satisfactorily resolved by the Kalman filtering.[8] The use of this filter is not limited to pseudo first-order reactions; in fact, it also allows the resolution of mixtures of species following different kinetics (pseudo-first order and second order).[13] The filter model used for this purpose was assessed both on simulated data and on the analysis of cysteine–ascorbic acid and gluthatione–ascorbic acid mixtures, which were resolved with good accuracy over wide concentration ranges.

4.3 Artificial Neural Networks

ANN, also called computational neural networks (CNN), are increasingly used in analytical chemistry owing to

their ability to "learn" arbitrary nonlinear relationships between input and output spaces.[8] An ANN can adapt itself autonomously to learn to recognize key features in a data set by repeatedly examining the same or similar data (the training set). ANNs can process information rapidly once the system is trained since the training process may require several hours of dedicated computer time depending on the particular training method. Several training methods have so far been used, the multilayer back-propagation method being the most widely employed so far.

The intrinsic features of ANNs afford the resolution of complex mixtures of species without the aid of spectral discrimination[14] even if the systems involved have almost identical rate constants and exhibit synergism. By contrast, multivariate calibration methods (MCMs) such as nonlinear least-squares regression (NLR) and principal components regression (PCR) (and even the Kalman filter) are effective approaches to multicomponent kinetic determination when they combine kinetic and spectral discrimination (multiwavelength data) as shown in the next section.

The type and number of input data to be used in an ANN must be carefully chosen in order to ensure accurate results in the concentration of the mixture components, with minimal training costs. This has been accomplished by developing a straightforward methodology.[14] For a binary mixture, Equation (14) can be fitted to Equations (15), the exponential function using NLR:

$$\Delta D_t = \Delta D_T[1 - \exp(-\hat{k}t)] + C \qquad (15)$$

where ΔD_T and $\hat{k}$ are related to the true values of ΔD_A, ΔD_B, k_A and k_B. $\hat{k}$ can be considered the estimated rate constant for the mixture, which approaches k_A as the contribution of component A in the mixture increases and vice versa. ΔD_T and $\hat{k}$ values obtained from the kinetic curve for the mixture concerned were used as input to the ANN in order to obtain ΔD_A and ΔD_B or the mixture concentrations as output data by means of a very simple neural network architecture such as 2:4s:2l (which means 2 input data, 4 nodes in the hidden layer and 2 output data) with no prior knowledge of the respective rate constants. A scheme of the operating mode of an ANN corresponding to this architecture is shown in Figure 3.

Figure 3 Schematic diagram of the foundation and architecture of the ANN used for multicomponent kinetic determinations. (Reproduced from Ventura et al., *Anal. Chem.*,[14] by permission. Copyright (1995) American Chemical Society.)

This method was evaluated in the resolution of mixtures of 2-chlorophenol (2-ChPh) and 3-chlorophenol (3-ChPh) (rate constant ratio 1.4) with fairly good results: the values of the relative standard error of prediction (%SEP) were 4.23 and 6.20%, respectively, and the analyte concentration ratio range was 1:9–9:1. The performance of the method compared favorably with that of the Kalman filter (Table 2), which yielded relative errors near

Table 2 Comparison of the quality achieved in the resolution of 2-ChPh/3-ChPh mixtures using ANNs and Kalman filter[a]

[2-ChPh]/[3-ChPh]	ANNs error (%)		Kalman filtering error (%)	
	2-ChPh	3-ChPh	2-ChPh	3-ChPh
9:1	2.41	−10.87	−2.50	39.5

[b] The Kalman filter results at these ratios correspond to exactly 2.3:1, 1:1.5 and 1:2.3, respectively.

to or about 10% in the resolution of 2-ChPh–3-ChPh mixtures in ratios from only 4:1 to 1:4.[14] On the other hand, the proposed network architecture could be extrapolated to multicomponent analysis involving other kinetic situations such as species following different kinetics and the presence of synergistic effects. However, realizing the actual potential of ANNs in kinetic analysis requires further research.

5 SPECTRAL/INSTRUMENTAL DISCRIMINATION

The kinetic methods described in this section are also based on mathematical algorithms but rely heavily on the spectral discrimination afforded by multiwavelength data simultaneously provided by special optical spectroscopic devices (instrumental discrimination) such as diode array spectroscopy and the use of T-optic configurations. In general, kinetic discrimination is also present to a greater or lesser extent. However, the use of multiple wavelengths allows systems having rate constants too close for analysis by normal means to be successfully determined provided they exhibit any spectral differences. In some cases, instrumental discrimination enables the kinetic determination of mixture components irrespective of their kinetics provided sufficient spectral differences between them exist.

5.1 Multivariate Methods Using Multiwavelength Spectroscopy

The use of several wavelengths in kinetic experiments allows a greater variety of systems to be successfully analyzed. In fact, rapid-scanning spectrophotometers such as diode array models were the earliest instruments used to perform multiwavelength studies in multicomponent kinetic analysis.[5,10] Full spectra can be recorded within a few seconds and simultaneous absorbance measurements made at several wavelengths instead of the absorbance–time data provided by conventional instrumentation are used as kinetic data. Thus, for a kinetic reaction involving a single component at an initial concentration C_0, absorbance changes with time can be expressed by Equation (16)

$$A_{\lambda,t} = \varepsilon_\lambda l C_0[1 - \exp(-kt)] + B_{\lambda,C} \tag{16}$$

For a mixture of two components 1 and 2 the absorbance is given by Equation (17)

$$A_{\lambda,t} = \varepsilon_{\lambda,1} l C_{0.1}[1 - \exp(-k_1 t)] + \varepsilon_{\lambda,2} l C_{0.2}[1 - \exp(-k_2 t)] + B_{\lambda,C} \tag{17}$$

Finally, for a mixture of n components, the simplified expression in Equation (18) holds:

$$A_{\lambda,t} = \sum_{i=1}^{n} K_{(i,\lambda,t)} C_{0.i} + B_{\lambda,c} \tag{18}$$

where $A_{\lambda,t}$ is the absorbance measured at wavelength λ at time t, $\varepsilon_{\lambda,\,1\ldots n}$ are the molar absorptivities of the components at the working wavelength, ℓ is the pathlength, $C_{0.1\ldots n}$ is the initial concentration of each component, $k_{1\ldots n}$ are the respective rate constants, $B_{\lambda C}$ is the background absorbance at $t = 0$ and $K_{(1,\lambda,t)}$ is a constant which depends on the particular component, its rate constant, wavelength and time.

Equation (18) is in itself a system of nonlinear equations that can be solved using various chemometric procedures such as the Newton–Gauss algorithm.[15] Although the molar absorptivity, rate constant and concentration of each mixture component can be determined simultaneously, the most interesting application is the determination of rate constants and concentrations as a compromise between computational costs and the ability to introduce corrective actions for fluctuations in the rate constants arising from environmental factors (error-compensated method), taking into account that absorptivities can be calculated individually with greater accuracy from equilibrium data.

The resolution of cobalt and nickel in mixtures (including the estimation of the rate constant) using the ligand-exchange reaction with EGTA (ethylene glycol bis(2-aminoethyl ether *N*,*N*,*N*′,*N*′-tetraacetic acid)) and PAR (4-(2-piridylazo)resorcinol) is one of the systems most widely used to validitate this approach.[15]

The application of the MCM to multicomponent kinetic analyses entails making several mixtures of known composition and recording their absorbances at different wavelengths and times. The wealth of information thus obtained must be reduced in order to abstract the analytically relevant information by using principal component analysis (PCA); also, calibration can be performed by using two similar MCMs such as PCR and partial least-squares regression (PLS). PLS breaks down both the measured data and the concentration calibration matrices into the product of two smaller matrices. This involves a data compression step where the measured absorbances are reduced to a small number of values called ''scores'' in a new coordinate system. The new axes are called ''principal components'' or ''factors''. PLS assumes a linear relationship between the concentrations and scores. The regression coefficients from each original variable to each principal component are called ''loadings''. Once the model has been fully developed, it can be used to determine analyte concentrations simply by using the data set for mixtures of unknown concentrations.

The effect of different variables (e.g. the influence of noise on both the analytical signal and the rate constants) on the quality of resolution of binary mixtures by PLS has also been assessed from simulated data, as has the potential of this algorithm for multicomponent kinetic determinations in nonlinear systems (e.g. in the presence of synergistic effects).[16] In contrast to curve-fitting and Kalman filtering approaches, these MCMs require no prior knowledge of rate constants or absorbance coefficients and entail no explicit adoption of a given kinetic model. Regarding the rate constant ratio for mixture components, because the resolution of the mixture relies on both spectral and kinetic discrimination, even mixtures of more than two components with near-unity ratios can be resolved. However, the rate constant ratio has a great influence on the mixture resolution in the presence of synergistic effects (it must be higher than three), as shown by applying PLS to simulated data.[16]

On the other hand, a procedure based on factor analysis was satisfactorily applied to kinetic data simulated from Gaussian and real spectra for Co(II) and Ni(II) using the above-mentioned ligand exchange reaction.[17]

Kalman filtering is a more effective approach when it is combined with spectral discrimination. Thus, the extended form of this algorithm has been fostered by combination with multiwavelength photometric determination, which is particularly effective for the simultaneous kinetic resolution of complex mixtures. Simulations have shown that mixtures can be successfully determined even if the rate constants of the two reactants are identical, as long as some spectral difference existed.[18] Quencer and Crouch[19] established the basis for the simultaneous determination of species from both their spectral and kinetic differences. Their approach allows resolution of more closely related species, thanks to the fast computation capabilities derived from the recursive nature of the Kalman filter. How large the differences need be to ensure accurate results depends on the number of wavelengths used for analysis; however, the larger the number of wavelengths used, the stronger is the overlap that can be tolerated. The accuracy of the determination is very good, even with a high degree of overlap and a few wavelengths; also, systems with completely overlapped kinetics can be resolved provided spectral differences exist at the chosen wavelength, and systems with completely overlapped spectra can be successfully determined as long as sufficient kinetic differences exist.[19] In the latter case, rate constants must differ by a factor of about 2.5–3 for acceptable results to be achieved using the extended Kalman filter.

5.2 Kinetic Wavelength-pair and H-Point Methods

Although the principle of these methods is different, both have been developed for the ultraviolet–visible spectroscopic kinetic analysis of two-component systems involving the selection of one or two wavelength pairs.

The *kinetic wavelength-pair* or *dual wavelength method*[20] involves measuring the difference in the rate of change of absorbance as a function of time at two preset wavelength pairs. The rate of change of absorbance, $u = \Delta A/\Delta t$, is dependent on the wavelength used and should not be confused with the chemical reaction rate, which is the same at any wavelength for a given concentration. The aim of this method is to enhance the accuracy in simultaneous multicomponent resolutions by increasing the differences between the absorptivity coefficient ratios of the components in the mixture at the preset wavelengths. A diode array spectrophotometer and a computer furnished with suitable software are required for application of this method.

For a mixture of two components M and N, it application involves measuring u at two wavelength pairs, (λ_1, λ_2) and (λ_3, λ_4) (for simplicity subscripts 1–4 in the expressions below denote measurements made at λ_1–λ_4 respectively), which are chosen in such a way that the difference between the rates of change of the absorbance for the first wavelength pair is as large as possible for one of the components (e.g. N), and the opposite holds for the second wavelength pair. The data set thus obtained allows determination of the concentrations of M and N in the mixture by using a single aliquot. Hence, if additivity of the rates of absorbance change at each wavelength is fulfilled, Equation (19) follows:

$$u_i = \left(\frac{\Delta A}{\Delta t}\right)_{\mathrm{M},i} + \left(\frac{\Delta A}{\Delta t}\right)_{\mathrm{N},i} \tag{19}$$

where i is the selected wavelength.

Taking into account the differences between wavelength pairs, the following systems of Equations (20) and (21) can be established:

$$u_2 - u_1 = \left(\frac{\Delta A}{\Delta t}\right)_{\mathrm{M},2} + \left(\frac{\Delta A}{\Delta t}\right)_{\mathrm{N},2} - \left(\frac{\Delta A}{\Delta t}\right)_{\mathrm{M},1} - \left(\frac{\Delta A}{\Delta t}\right)_{\mathrm{N},1} \tag{20}$$

$$u_4 - u_3 = \left(\frac{\Delta A}{\Delta t}\right)_{\mathrm{M},4} + \left(\frac{\Delta A}{\Delta t}\right)_{\mathrm{N},4} - \left(\frac{\Delta A}{\Delta t}\right)_{\mathrm{M},3} - \left(\frac{\Delta A}{\Delta t}\right)_{\mathrm{N},3} \tag{21}$$

where $u_2 > u_1$ and $u_4 > u_3$.

Parameter u is related to the chemical reaction rate, v, through Equation (22) and (23):

$$v_M = \frac{\Delta[M]}{\Delta t} = \frac{1}{\varepsilon_{M,i}} \left(\frac{\Delta A}{\Delta t} \right)_{M,i} = k_M[M] \quad (22)$$

$$v_N = \frac{\Delta[N]}{\Delta t} = \frac{1}{\varepsilon_{N,i}} \left(\frac{\Delta A}{\Delta t} \right)_{N,i} = k_N[N] \quad (23)$$

where k_M and k_N are the first-order rate constants and a path length of 1 cm is assumed. A combination of Equations (20), (21), (22) and (23) yields Equations (24) and (25):

$$u_{2-1} = u_2 - u_1 = k_M(\varepsilon_{M,2} - \varepsilon_{M,1})[M] + k_N(\varepsilon_{N,2} - \varepsilon_{N,1})[N] \quad (24)$$

$$u_{4-3} = u_4 - u_3 = k_M(\varepsilon_{M,4} - \varepsilon_{M,3})[M] + k_N(\varepsilon_{N,4} - \varepsilon_{N,3})[N] \quad (25)$$

which allows the concentrations of M and N to be simultaneously determined.

The four wavelengths used are selected and u calculated by computer. The conditions yielding the most accurate and sensitive estimate of M and N concentrations are those at which the differences between $(\varepsilon_{M,2} - \varepsilon_{M,1})/(\varepsilon_{N,2} - \varepsilon_{N,1})$ and $(\varepsilon_{M,4} - \varepsilon_{M,3})/(\varepsilon_{N,4} - \varepsilon_{N,3})$ are maximal and parameters $u_2 - u_1$ and $u_4 - u_3$ are as large as possible.

Considerable simplification is introduced when only one component contributes at each wavelength pair (e.g. $(\Delta A/\Delta t)_{N,2} = (\Delta A/\Delta t)_{N,1}$ and $(\Delta A/\Delta t)_{N,4} = (\Delta A/\Delta t)_{N,3}$). In that case, Equations (24) and (25) become Equations (26) and (27)

$$u_M = u_2 - u_1 = k_M(\varepsilon_{M,2} - \varepsilon_{M,1})[M] \quad (26)$$

$$u_N = u_4 - u_3 = k_N(\varepsilon_{N,4} - \varepsilon_{N,3})[N] \quad (27)$$

Hence u_M is independent of the concentration of N and u_N is independent of that of M.

The kinetic wavelength-pair method considerably enhances accuracy relative to some classical kinetic approaches (e.g. logarithmic extrapolation, single point and proportional equation methods), as shown in the simultaneous determination of formaldehyde and acrolein by reaction with 3-methylbenzodiazolin-2-one hydrazone.[20]

There are some advantages associated with the use of the kinetic wavelength-pair method. Thus, the resolution is based on kinetic and spectral differences. Therefore, the simultaneous kinetic determination of species with rate constant ratios close to unity is possible whenever enough spectral differences exist. On the other hand, application of the method requires no use of complex chemometric procedures and, in principle, there are no restrictions with regard to the number of components that can be determined. Its main drawback is a low sensitivity compared with methods based on peak wavelengths. The method has also been extended to the fixed-time kinetic approach[21] and has been applied to the resolution of binary mixtures of arsenate and phosphate,[21] *o*-cresol and *m*-cresol,[22] as well as to ternary mixtures of phenothiazines.[23]

The *H-point standard addition method* (HPSAM)[24] is identificated for two cases, namely the determination of two species of which only one evolves with time, and that of two species with overlapped time evolutions.

For a mixture of two components C_1 and C_2, the determination of the concentration of C_1 at equilibrium by the HPSAM entails selecting two wavelengths, λ_1 and λ_2, lying on each side of the absorption maximum of C_2 so that the absorbance of the latter component is the same at both wavelengths. Then, known amounts of C_1 are successively added to the mixture and the resulting absorbances at the two wavelengths are measured. The two straight lines thus obtained intersect at the so-called H-point $(-C_H, A_H)$, where $-C_H = (-C_{C_1})$ is the unknown concentration of C_1 and $A_H = (A_{C_2})$ is the analytical signal of C_2. When one of the species evolves with time, the variables to be fixed are two times, t_1 and t_2. Species C_2, which should not evolve with time over this range, should have constant absorbance. This contrasts with the equilibrium HPSAM, where two wavelengths are chosen. A plot is then constructed of added $[C_1]$ on the y-axis and ΔA for the two times on the x-axis. The point where $\Delta A = 0$ is equal to $-[C_1]$.

When both species evolve with time, $[C_1]$ can be calculated by plotting ΔA for the two times against the added concentration of C_1 at two wavelengths λ_1 and λ_2 provided the absorbances of C_2 at these two wavelengths are the same.

5.3 Miscellaneous Methods

The continuous addition of reagent (CAR) technique[25] is also applicable to multicomponent kinetic determinations. This method allows the resolution of mixtures of species basically thanks to the special way in which sample and reagents are mixed, discrimination being mainly of the instrumental type.

This method is based on the continuous addition of a reagent at a constant rate to the species to be determined.[25] The model for this method was developed for a single component but has readily been extended to multiple reacting species. If a solution of a reagent R of concentration $[R]_0$ is added at a constant rate u to a volume V_0 of a solution containing the analyte C, then the overall rate of the process will be given by Equation (28)

$$-\frac{d[C]}{dt} = k \left(\frac{u[R]_0}{V_0} \right)_{t[C]_0} \quad (28)$$

on the assumption that, under short reaction times, dilution of the analytes can be neglected. k is the second-order reaction rate. Equation (28) is used to construct a linear calibration graph by plotting the initial slopes of the kinetic curves as a function of $[C]_0$ over a fixed time interval in all experiments.

Two or more kinetic curves corresponding to as many components are sequentially obtained by recording the changes in the analytical signal as function of time; the respective slopes are proportional to the individual concentration of each component.[26] The reactions of mixtures whose components react very rapidly under pseudo first-order conditions are slowed on switching to pseudo second-order kinetic conditions, which allows the separation of the analytes on different timescales according to their reactivities and reaction rates. These reactions are independent of each other and are related to the characteristic parameters of the CAR technique shown above and to the concentration of each component through Equation (28), established from initial rate measurements. For a mixture of two components A and B these reaction rates are given by Equations (29) and (30)[26]

$$-\frac{\mathrm{d}[\mathrm{A}]}{\mathrm{d}t} = k_{\mathrm{A}}\left(\frac{u[\mathrm{R}]_0}{V_0} \quad t[\mathrm{A}]_0 \right. \tag{29}$$

$$-\frac{\mathrm{d}[\mathrm{B}]}{\mathrm{d}t} = k_{\mathrm{B}}\left(\frac{u[\mathrm{R}]_0}{V_0} \quad t[\mathrm{B}]_0 \right. \tag{30}$$

If $k_{\mathrm{A}} > k_{\mathrm{B}}$, only component A will react with the reagent, R, added from the autoburette; once component A has almost completely reacted, the addition of a fresh volume of R starts the reaction of component B and the concentrations of A and B are calculated from Equations (29) and (30), respectively. This method involves no complex mathematical treatment and can also be used to resolve multicomponent mixtures by using n equations in unknowns, provided appropriate values of adequate k_n/k_{n-1}, k_{n-1}/k_{n-2} and so on can be obtained in order to minimize errors.

Figure 4 Absorbance–time curve provided by the CAR technique for a mixture containing $1.2\,\mu g\,mL^{-1}$ zineb and maneb. (Reproduced by permission of the Royal Society of Chemistry, from Quintero et al.[27])

Mixtures of metal ions such as copper(II) and iron(III),[26] and pesticides such as zineb and maneb,[27] have been resolved by using complex-formation reactions in both cases. Figure 4 shows the absorbance–time curve obtained for a mixture of zineb and maneb.

6 PHYSICOCHEMICAL DISCRIMINATION: MICELLAR CATALYSIS

Micellar catalysis can be a powerful tool for implementation of differential reaction rate methods. Micelles can alter the apparent rate constant ratio of two or more species that interact with a common reagent by both altering their intrinsic reactivity and, more generally, binding to a different extent to different analytes. According to the pseudophase model,[28] the observed second-order rate constant for a bimolecular reaction between A and B in the presence of micelles, k_{exp}, is given by Equation (31)

$$k_{\mathrm{exp}} = \frac{(k_{\mathrm{M}}P_{\mathrm{A}}P_{\mathrm{B}} + k'_{\mathrm{M}}P_{\mathrm{A}} + k''_{\mathrm{M}}P_{\mathrm{B}})CV + k_{\mathrm{W}}(1 - CV)}{(1 + K_{\mathrm{A}}C)(1 + K_{\mathrm{B}}C)} \tag{31}$$

where the subscripts M, w, A and B denote quantities related to the micellar phase, aqueous phase and reactants, respectively; P_{A} and P_{B} are the partition coefficients of the reactants (i.e. $P_{\mathrm{A}} = [\mathrm{A}]_{\mathrm{M}}/[\mathrm{A}]_{\mathrm{w}}$); C is the surfactant concentration (molarity) minus the critical micelle concentration; V is the molar volume of surfactant; the factors CV and $(1 - CV)$ are the volume fractions of the micellar and aqueous phase, respectively; and K_{A} and K_{B} are the binding constants of the reactants, viz. $K_{\mathrm{A}} = (P_{\mathrm{A}} - 1)V$ and $K_{\mathrm{B}} = (P_{\mathrm{B}} - 1)V$; k_{M} and k_{w} denote the rate constants of the reactions taking place in the micellar and aqueous phase, respectively; k'_{M} is the rate constant of the reaction resulting from collisions between reactant A in the micellar phase and reactant B in the aqueous phase, and k''_{M} is the rate constant of the reaction between reactant B in the micellar phase and reactant A in the aqueous phase.

The efficiency of micellar catalysis, a parameter of interest in kinetic methodology, will be given by the ratio $(k_{\mathrm{exp}}/k_{\mathrm{w}})$, which depends on two factors, Equation (32):

$$\frac{k_{\mathrm{exp}}}{k_{\mathrm{w}}} = \frac{k_{\mathrm{M}}}{k_{\mathrm{w}}}\frac{K_{\mathrm{A}}K_{\mathrm{B}}}{V(\sqrt{K_{\mathrm{A}}} + \sqrt{K_{\mathrm{B}}})^2} \tag{32}$$

The first factor $(k_{\mathrm{M}}/k_{\mathrm{w}})$ takes into account the changes in intrinsic reactivity when the reactants are transferred

from water into the micelle phase and hence the specific effect of the micelles on the transition state of the reaction. The second factor depends on the effective reactant concentration in the micellar pseudophase and is dependent on the binding constants of the reactants to the micelles (K_A, K_B) and the molar volume of the surfactant (V). Analysis of different reactions developed in the presence of micelles in the light of different models showed that the observed increase in the reaction rate was mainly caused by the reactant concentrating in a low volume in the micellar pseudo-phase since the values of k_M and k_w were similar.

For two analytes with different partition coefficients, the ratio between their rate constants will depend on the surfactant concentration. As a result, micellar aggregates might be useful for the resolution of mixtures of species with similar reactivities in aqueous media or in those cases where a given component takes too long to react and thus precludes analytical measurements.

There are many other features of micellar aggregates that can be of great value in multicomponent kinetic analysis, Thus, micelles have been used to alter reaction pathways, modify the mechanisms through which these reactions develop and alter product distribution in reactions where two or more products are generated. Consequently, micelles can alter the physicochemical features of the reactant or product of the reaction concerned and give rise to spectral shifts, changes in molar absorptivity and so on, which make them firm candidates for kinetic multicomponent analysis.

Micellar catalysis has been applied to the determination of binary mixtures of cyanide, sulfide and sulfite based on their reaction with 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB).[29] The anion mixture could not be resolved by conventional differential kinetic analysis in an aqueous medium because of the similar reactivity of sulfide and sulfite ions and the slowness of the reaction between cyanide and DTNB, which took ca. 100 min to complete. The dependences obtained by plotting the observed rate constants, k_{exp}, of the reactions among the three ions and DTNB as a function of the cetyltrimethylammonium bromide (CTAB) concentrations (Figure 5) showed that, by selecting an appropriate concentration of surfactant, adequate differences between the rate constants were obtained and binary mixtures of the anions at micromolar concentrations could be resolved by using a multiple linear regression method.

Micellar control of reaction pathways leading to specific products can be of great use in multicomponent kinetic analysis. One representative example of the potential of

Figure 5 Dependence of the rate constants for the sulfide–DTNB, (1) sulfite–DTNB (2) and cyanide–DTNB (3, 4) systems on the CTAB concentration. Curves 1, 2, 4 obtained at pH 8; curve 3 obtained at pH 10. (Reproduced from González et al., *Anal. Chem.*, [29] by permission. Copyright (1993) American Chemical Society.)

this micellar effect is the simultaneous determination of V(V), Cr(VI) and Ti(IV) based on their reactions with pyrogallol red (PR) in the presence of dodecyltrimethylammonium bromide (DTAB) micelles.[30] In an aqueous medium, PR is gradually decolorized by oxidation with chromium(VI) and vanadium(V), so the simultaneous resolution of these two ions is rendered impossible by their similar reactivity. Titanium(IV) interferes with the individual determinations of these ions by forming a complex with PR. DTAB micelles have the following effects on the process: they catalyze the oxidation of PR by Cr(VI); they allow the oxidation reaction between V(V) and PR to be completely displaced by a complex-formation reaction between the two species, and they also alter the photometric features of the Ti(IV)–PR complex. These changes allow the simultaneous resolution of the three ions from measurements made at three different wavelengths corresponding to as many reaction products. The linear determination ranges thus achieved are between 0.2 and 1 μg mL^{-1} and the relative errors made in the resolution of the ternary mixture vary from 0.7 to 1.4%.

The use of micellar media can be a powerful tool for enhancing kinetic determinations and facilitating kinetic multicomponent analyses.

7 PRACTICAL IMPLEMENTATION: AUTOMATED METHODS

The conversion of differential kinetic methods of purely academic interest into practical methods for routine analysis entails a certain degree of automation. Electronic devices and computers have played a decisive role insofar as they have solved the problems associated with the measurement of time (i.e. especially in fast processes) by permitting automated acquisition of data during development of the process. Differential kinetic methods use instruments of varying degrees of complexity, from conventional elementary systems to sophisticated, completely automated instruments capable of collecting the sample, transporting it to the detector and processing the results obtained. This latter trend has been significantly fostered by the development of automated instrumentation for the computation of reaction rates such as the incorporation of SF mixing chambers into conventional photometric (including diode array) or fluorimetric detectors (for fluorescence or chemiluminescence measurements), the use of a simple automatic titrators and the implementation of continuous-flow techniques on simple manifolds, among others.[2,4,31,32]

Kinetic measurements are free from effects of factors that introduce errors in absolute values (e.g. turbidity, the presence of other absorbing or fluorescent substances provided they do not take part in the reaction of interest or alter the parameter response); as a result they are based on temporal charges in the parameter used to monitor the reaction (absorbance, fluorescence, intensity, potential) rather than on their absolute values. However, strict timing and temperature control (to within 0.01–0.1 °C) are essential for kinetic methods, which thus require modern powerful instrumentation. The choice of a given method for implementing rate measurements of a reaction is dictated by its half life. Thus, the instrumentation required to monitor slow reactions is typically simpler than that needed for fast reactions.

The process involved in measuring the rate of two or more components in a sample by using a common reagent comprises the following steps:

1. preparation, measurement, transport and mixing of reactants
2. signal monitoring and transducing at a constant temperature by measuring changes in a property of the reactants or products
3. timed acquisition of data (viz. collection of signals at different times) which are simultaneously or sequentially processed, usually with the aid of a computer.

Fully automated systems execute all three steps above, whereas partly automated instruments usually perform steps (2) and (3) only, and process data in a sequential rather than simultaneous manner.

In this section are briefly described currently available mixing modes and instrumental measurements such as flow techniques (low-pressure continuous and high-pressure SF techniques), used with single- or multi-wavelength photometric detection and luminescence detection, and the low-pressure CAR technique with photometric or luminescence detection, in addition to other approaches such as the T-optical fluorescence technique.

The increasing popularity of multicomponent kinetic methods is reflected in the variety of real analytical problems which are currently being addressed with their help.[4,31]

7.1 Mixing Modes and Instrumental Assemblies

The first step in the kinetic process, that is the mixing of sample and reagents, is common to other analytical methods but is a key step in kinetic methods as it involves measuring the parameter via which the process is monitored. The way in which reactants are mixed to start the analytical reaction depends on whether the external experimental conditions will remain unchanged (closed systems) or not (open systems). Closed systems are unsuitable for fast reactions while open systems are specially suited to reactions with fast kinetics. The sample must be thoroughly mixed with the reagent(s) at a constant temperature before it is transferred to the detection system for measurement. This can be done manually, which is usually the case with closed systems, or automatically. Manual mixing can be accomplished simply by homogenizing the reactants in the reaction vessel, which can be a spectrophotometric cuvette or an electrode cell. The instant at which the last reactant is added is taken as the reaction start time ($t = 0$) and must therefore be determined with great accuracy.

Automated mixing of sample and reagents calls for special mechanical/electronic devices when fast reactions, which as noted earlier require the use of open systems, are addressed. This increases the reproducibility and throughput of multicomponent kinetic analysis and is the reason why automated open systems are preferable even when slow reactions are involved.

The most frequently used open systems can be classified into continuous or flow systems and discrete systems. The most popular and widely employed techniques in connection with such systems for multicomponent kinetic determinations in routine analyses are flow injection and SF among the former and the CAR technique among discrete systems.

As a rule, the flow rate of the sample and/or reagents in the mixing system can be zero or constant while the kinetic curve is being recorded. The former alternative is the basis for SF systems; on the other hand, in continuous addition analyses, the flow rate of one of the reaction ingredients is nonzero and constant. Throughout the measurement interval, the reactants can be circulated at a given, identical flow rate in flow injection analyses.

SF is highly versatile and often superior to other flow techniques such as continuous-flow analysis (CFA), both in its air-segmented CFA and in its unsegmented mode (flow-injection analysis, FIA). Thus, SF can be applied to the resolution of mixtures following very fast kinetics with higher sample throughput and lower reagent consumption than those afforded by FIA or CFA.

The choice of a given technique will be dictated not only by its technical features, but also by the half lives of the reactions concerned as shown below.

7.2 High-pressure Stopped-flow Technique

This technique is the most commonly used for the resolution of mixtures involving fast reactions (namely those with half lives of a few milliseconds to a few seconds). In conventional SF systems, the sample and reagents are mixed at high pressure by means of two driving syringes that are actuated manually or automatically (e.g. by pneumatic device) which are inserted into a flow cell or mixing chamber that can also act as the observation cell. The flow is then abruptly stopped by using a third syringe and the analytical signal is recorded as a function of time. The system can be controlled by computer which can also be used for data acquisition and processing. The dead time of the instrument, which is determined by the mixing efficiency (viz. the mixing time) and the transport and stop times, must be smaller than the half life of the reaction of interest by about two orders of magnitude. The high cost of SF instruments (which has delayed its use in routine analyses) can be avoided by using commercially available SF mixing modules to fit to conventional and diode array photometric, fluorimetric and chemiluminescence detectors for implementation of the SF techniques. Figure 6 depicts a SF mixing module controlled by a simple computer interfaced on-line to it. The module is accomodated vertically above the detector.[33] This modular SF system is applicable to reactions with half lives in the millisecond range. Analytical results are rapidly obtained by using computer software for differential kinetic methods, this ensures high sample throughput, reproducibility and accuracy. The modular system has proved fairly efficient in the spectrophotometric or spectrofluorimetric determination of binary mixtures of metal ions, biogenic amines, drugs and pesticides.[4] Some of the ensuring methods are based on slow reactions, which also benefit from the simplicity, rapidity, precision and minimum sample and reagent manipulation of the SF technique.[4]

The above-described SF module was also incorporated into a commercial diode array spectrophotometer to resolve multicomponent mixtures by kinetic methodology. The ability to make absorbance measurements as a simultaneous function of time and wavelength is a powerful way of accomplishing kinetic multicomponent analyses, as shown in section 5. Two or more reactions involving the same or different reagents can be simultaneously monitored in this way. When the absorption spectra for the mixture components are sufficiently resolved (i.e. in the simplest case), kinetic data can be readily obtained at each absorption maximum without the need to apply differential kinetic methods based on mathematical approaches, provided the reaction rates of the components are independent of one another. Figure 7 shows the three-dimensional plot for a mixture of hydrazine and phenylhydrazine determined by their corresponding condensation reactions with *p*-dimethylaminobenzaldehyde (DAB), as well as their respective kinetic curves, which were computed simultaneously. These data allowed the individual and/or simultaneous determination of these compounds by applying a computerized initial-rate method.[34]

SF differential rate methods have also been applied to energy-transfer sensitized luminescence reactions based on the energy transfer from an excited organic compound analyte to europium or terbium ion which gives a characteristic line-type emission at 612 nm [Eu(III)] or 545 nm

Figure 6 Schematic diagram of a modular SF system. A, Driving and stopping syringes; B, mixing-observation chamber; C, pneumatic propulsion system; D, thermostatted chamber. (Reproduced by permission of the Royal Society of Chemistry, from Pérez-Bendito.[4])

[Tb(III)]. These methods rely on the different rates of formation of a lanthanide–analyte–ligand ternary complex in the presence of a surfactant, which is very fast and require the use of the SF technique. Tetracycline–doxycyclines in mixtures were simultaneously determined in this way, in untreated serum samples using the proportional equation method. The kinetic curves were obtained by placing Eu(III) and thenoyltrifluoroacetone (TTA) in one of the syringes and tetracycline plus Triton X-100 in the other.[35] A similar approach was also developed for the simultaneous determination of salicylic acid and diflunisal with terbium(III)–EDTA (*N*,*N*,*N*′,*N*′-ethylenediaminetetraacetic acid) and CTAB in a basic medium.[36]

7.3 Low-pressure Continuous Flow Techniques

The unsegmented continuous-flow technique, so also called ''FIA''[37] is one other automated approach for implementing the differential reaction rate method. Although it is unsuitable for fast reactions (mixing is not efficient enough owing to the low pressure in the merging streams and dispersion decreases the sensitivity) it has been used in multicomponent kinetic determinations by virtue of the very simple instrumental set-up required. Typically, this consists of a peristaltic pump for propelling a carrier, into which the sample is injected by means of an injection valve, and one or more reagent streams that merge at a mixing point and then pass through a reaction coil of appropriate length before they reach a flow-cell placed in the detector. The analytical signal is a sharp peak the height of which is directly related to the analyte concentration. The degree of complexity of this configuration depends on whether it includes one or several detectors, simple or multiple injection, whether or not it involves splitting or stopping the flow and so on.

Flow-injection differential reaction rate methods are essentially based on the formation of two reaction zones reacting in the detector at different times, the use of multiple detection points separated by delay coils or the iterative passage of the reacting plug by the same detection point. Depending on the type of data obtained, there are two basic types of flow-injection differential reaction-rate methods, that is those based on two signals measured at different reaction times and those relying on multipoint signal–time curves. From a practical point of view, the most outstanding differential reaction-rate methods implemented in simple flow manifolds rely on the formation of two reaction zones based on the differential contribution of each analyte to each peak resulting from differences in reaction rate. The mixture is resolved by applying the classical proportional equation method (section 3.1). One example is the analysis of mixtures of cobalt and nickel based on the formation of their complexes with 2-hydroxybenzaldehyde thiosemicarbazone.[38]

The other type of method involves the iterative passage of the reacting plug through a nondestructive detector in order to obtain multipeak recordings that can be used for kinetic purposes since the envelopes of their maxima and minima resemble typical kinetic curves.[39]

7.4 Low-pressure Continuous Addition of Reagent Technique

The special way in which the sample and reagents are mixed in this technique affords the resolution of mixtures by direct kinetic methods. The description and theoretical formulation of this technique are given in section 5.3. The experimental set-up for implementation of the CAR technique is shown in Figure 8. A typical CAR assembly consists of (1) an addition unit composed of an autoburette, a magnetic stirrer and a thermostatted vessel as reaction cell, (2) a photometric/fluorimetric or chemiluminescence detection unit that can includes an immersion probe for photometric measurements and (3) a computer. The reaction vessel can be of variable capacity from 60 mL to about 2 mL and typically holds sample volumes in the microliter range. This makes the technique especially useful when the amount of sample available is limited (e.g. with serum samples).

The CAR technique is a major alternative to the SF technique in tackling direct rate measurements of reactions with half lives of a few milliseconds, each component of the mixture is determined in a sequential manner in a single run of sample. Typical examples are the photometric determination of binary mixtures of carbamate pesticides (see Figure 4) in commercial formulations,[27] and of copper and iron in serum samples by use of a miniaturized reaction chamber[26] and photometric detection.

The CAR technique has also been used for the resolution of mixtures involving chemiluminescent reactions by using peroxyoxalate energy-transfer processes. 2,4-Trichlorophenylperoxyoxalate (TCPO) was added from the autoburette to the sample (a mixture of trimeprazine and methotrimeprazine) in excess hydrogen peroxide in the reaction vessel.[40] A single kinetic curve (sum of the two reactions) was obtained and the kinetometric ANN approach (see section 4.3) was used to resolve the mixture, the components of which exhibited a similar kinetic behavior and synergism. The CAR technique suppresses the background emission associated with this type of chemiluminescence reaction, thereby increasing the signal-to-noise ratio.

Figure 8 Experimental set-up for implementation of the CAR technique.

7.5 Miscellaneous Instrumental Approaches

Kinetic fluorimetric methods for the simultaneous resolution of mixtures usually involve chemical reactions that must meet several requirements when a conventional L-format spectrofluorimeter is used, namely: (1) similar maximum excitation and emission wavelengths for their reaction products and (2) differential kinetic behavior. In addition, if the reaction rate of any of the systems involved is very fast, the reactants cannot be mixed manually batchwise since the reaction is finished by the time the instrument starts acquiring the kinetic curve. However, the use of a spectrofluorimeter in a T-format configuration (one with two emission paths symmetrically arranged on both sides of the sample compartment), which is commercially available, allows two chemical systems with similar excitation wavalengths but different emission wavelengths to be monitored. The absence of overlap in the emission maxima allows kinetic data to be obtained from each individual system, even if both possess similar rate constants.

When the chemical system involves fast reactions, the combined use of one such spectrofluorimeter with the SF technique allows kinetic data to be obtained and provides a means for automation and rapid handling of reagents, both of which are highly desirable in routine analyses. Figure 9 shows a scheme of this approach, which provides ''instrumental discrimination'' for the resolution of neomycin and promethazine using two different reactions, namely *o*-phthaldialdehyde (OPA) in the presence of *N*-acetylcysteine to yield a fluorescent substituted isoindole by its condensation with neomycin and the oxidation of promethazine to a fluorescent sulfoxide by dissolved oxygen.[41] The sample solution, in a borate buffer medium, was placed in one of the syringes, the other being filled with an aqueous solution containing OPA, *N*-acetylcysteine and borate buffer. The common excitation wavelength used was 335 nm; the oxidation of promethazine was monitored on channel B at 370 nm and the condensation of neomycin on channel A at 460 nm. The respective kinetic data were processed by a microcomputer and the initial rate method was used to determine each component in the mixture.

Figure 9 Scheme showing the SF/T-format spectrofluorimetric approach.

Figure 11 Pt-electrode potential–time dependence for gallic acid and resorcinol perturbation on the oscillating reaction for 0.55 μmol of gallic acid and 6.0 μmol of resorcinol. (Reproduced from Jiménez-Prieto et al., *Anal. Chim. Acta.*[43] Copyright (1996) by permission of Elsevier Science.)

The introduction of the analyte pulse perturbation (APP) technique[42] has opened up new prospects for differential rate determinations based on oscillatory reactions, which are a special type of far-from-equilibrium dynamic system. This technique allows the steady state of an oscillating reaction to be rapidly restored after each perturbation with a microvolume of the analyte added to a continuous-flow stirred tank reactor (CSTR); this affords many determinations on the same oscillating system in a simple rapid manner. Thus, two or more different responses corresponding to as many components are sequentially obtained in the oscillating system; the respective perturbation (i.e. change in period or signal amplitude of the oscillating curves) is proportional to the individual concentration of each component.[43] This approach is very simple since it requires none of the complex mathematical treatments used in kinetometric approaches. Figure 10 shows a schematic depiction of the experimental set-up required for the resolution of gallic acid/resorcinol mixtures[43] based on their perturbation (Figure 11) on the copper(II)-catalyzed oscillating reaction between hydrogen peroxide and sodium thiocyanate, using the

Figure 10 Schematic depiction of the experimental set-up used for the resolution of gallic acid/resorcinol mixtures by the APP technique. (Reproduced from Jiménez-Prieto et al., *Anal. Chim. Acta.*[43] Copyright (1996) by permission of Elsevier Science.)

APP technique as implemented in a thermostatted CSTR, potentiometric detection, a peristaltic pump to dispense the reagent continuously and keep the volume in the CSTR constant, and a computer to acquire and process data.

8 MULTICOMPONENT KINETIC DETERMINATIONS AS PROBLEM SOLVERS

One of the best indicators of the consolidation of differential reaction-rate methods is their increasing use for solving real problems.[2,4]

Thus speciation has also been addressed by using these methods. Distinguishing between the forms (free or bound) or oxidation states in which a given species can occur in a sample is possible by applying differential rate methods. Fe(III) and Fe(II) can be simultaneously determined in iron-rich groundwater through the aerial oxidation of Fe(II) in the presence of Tiron and acetate ion; the Fe(III) formed is subsequently complexed with Tiron and the reaction is monitored spectrophotometrically. The concentrations of Fe(III) and Fe(II) are obtained from the initial and equilibrium absorbance values, respectively, which are calculated by nonlinear least-squares fitting (without the need for any prior rate constant measurement).[44] The same iron ions were determined in wines by the formation of the Fe(III)–thiocyanate complex, using the SF technique to process the two samples needed for analysis.[33] In the speciation of Sb(III) and Sb(V), the differential rate of reaction of the two ions with mandelic acid enabled their discrimination.[45] The different forms in which a metal ion can occur in a given medium such as water or soil (e.g. free, complexed or bound to organic molecules) can be discriminated by adapting conventional differential reaction-rate methods to the analysis of mixtures for which neither the number of components nor their rate constants is known. Such is the case with the kinetic speciation of Ni(II) bound to fulvic acid in a soil.[46]

Differential kinetic analyses have also proved useful in various analytical areas of interest such as environmental and clinical chemistry for the determination of organic and inorganic species in mixtures. Mixtures of carbamate pesticides (e.g. carbaryl + 1-naphthol, carbaryl + 1-naphthol + 2-naphthol and carbofuran + propoxur) in different types of water samples were resolved with satisfactory results by the SF technique.[4] The micellar catalysis approach described in section 6 was also applied to the simultaneous kinetic determination of arsenate and phosphate in water samples.[47] Mixtures of epinephrine and norepinephrine in urine[48] were resolved by the automatic method described in section 7.2. Mixtures of phenothiazines in human serum samples,[23] and *o*-cresol and *m*-cresol in urine samples,[22] were resolved based on their respective oxidative coupling reactions, which exhibit strong kinetic and spectral overlap, using the kinetic wavelength pair-method described in section 5.2. These are but a few examples of the uses of differential rate methods with clinical samples that involve little or no sample treatment.

Pharmaceutical analysis has also benefited from differential rate methods.[49] Thus, psychotropic drugs such as epinephrine and norepinephrine, chlorpromazine and perphenazine, and thiamine and cocarboxylase, among others, have been determined in different pharmaceutical preparations by using (mainly) proportional equation methods. Differential rate methods have also been applied to food analysis. Thus, the simultaneous determination of ampicillin and tetracycline in milk[50] was accomplished by using the SF/T-format spectrofluorimeter described in section 7.5, as was the resolution of mixtures of the antioxidants butylated hydroxyanisole and propyl gallate in commercial food samples (chicken and vegetable group, corn, sunflower, olive oils, and margarine) using SF diode array detection.[51]

Most of these methods feature high sampling rates and have been promoted by the inception of the above-described automatic techniques. The expeditiousness with which samples can be processed and the ease with which the data produced can be treated have helped popularize multicomponent analytes by differential rate methods.

ACKNOWLEDGMENT

The author gratefully acknowledges financial support from Spain's DGICyT (Project PB96-0984).

ABBREVIATIONS AND ACRONYMS

ANN	Artificial Neural Network
APP	Analyte Pulse Perturbation
CAR	Continuous Addition of Reagent
CFA	Continuous-flow Analysis
CNN	Computational Neural Network
CSTR	Continuous-flow Stirred Tank Reactor
CTAB	Cetyltrimethylammonium bromide
DAB	*p*-Dimethylaminobenzaldehyde
DTAB	Dodecyltrimethylammonium bromide
DTNB	5,5′-Dithiobis(2-nitrobenzoic acid)
EDTA	*N*,*N*,*N*′,*N*′-Ethylenediaminetetraacetic Acid

EGTA	Ethylene Glycol bis(2-aminoethyl ether *N*,*N*,*N*′,*N*′-tetraacetic acid)
FIA	Flow-injection Analysis
HPSAM	H-Point Standard Addition Method
MCM	Multivariate Calibration Method
NLR	Nonlinear Least-squares Regression
OPA	*o*-Phthaldialdehyde
PAR	4-(2-Piridylazo)resorcinol
PCA	Principal Component Analysis
PCR	Principal Components Regression
PLS	Partial Least-squares Regression
PR	Pyrogallol Red
PTSC	Pyridoxal Thiosemicarbazone
SEP	Relative Standard Error of Prediction
SF	Stopped-flow
TCPO	Trichlorophenylperoxyoxalate
TTA	Thenoyltrifluoroacetone
2-ChPh	2-Chlorophenol
3-ChPh	3-Chlorophenol
